"The practical lesson is, that it is better to have the lambs dropped as early as possible in winter, supposing that food and shelter suitable are provided, for in winter there is very little likelihood of their becoming infested with parasites; then they should be pushed rapidly forward while suckling their mother, and weaned, if of suitable age, when first ready to turn on grass. They ought then to have fresh pasture that has had no sheep on it for two years, or at least that had no sheep the preceding year, and no old sheep should be pastured with the lambs."

Methods of combating communicable diseases of farm animals, R. R. DINWIDDIE (*Arkansas Sta. Bul. 51, pp. 35-46*).—The cause and origin of communicable diseases, general methods of prevention and control, inoculation against anthrax or charbon, and prevention and control of Texas cattle fever are briefly touched upon. The methods of control, etc., noted are such as are applicable to all contagious animal diseases and such as should readily suggest themselves to intelligent owners of live stock; but, in the author's opinion, they are generally

neglected or carried out in a half-hearted manner and are therefore ineffectual.

Communicable diseases, aside from the primary cases (disease germs), are noted as due to the introduction of diseased stock, exposure of animals to diseased stock of neighbors, to infected drinking water, and such miscellaneous agencies as man, dogs, birds, insects, etc. Proper isolation, the use of water from deep wells, runs, or pastures of sufficient size, and disinfection of pens, are insisted upon.

Anthrax is not thought to be endemic in this country. Inoculation against it is not regarded with favor, since there seems to be danger of continuing the disease by this means.

Texas fever may be controlled by washes of pyrethrum, kerosene emulsion, and kerosene emulsion in connection with the liberal use of a currycomb and hand picking. Dips are not thought successful. The presence or absence of ticks in the region is not thought a reliable test for the presence or absence of the disease. For noninfectious diseases the method is the obvious one of introducing no stock from infected localities.

Tuberculin investigations in Sweden, J. SVENSSON (*Ber. Andra Nord. Landtbr. Kongr., Stockholm, 1897, I, pp. 229-240*).—The first systematic tests in Sweden for tuberculosis by the injection of tuberculin were made in April, 1895. During the following 2 years and 2 months 35,992 cattle, distributed on 1,117 farms, have been inoculated. Of this number 52.6 per cent did not give any reaction, 5.2 per cent were doubtful, and 42.2 per cent gave a decided reaction. The animals examined were largely in herds on large estates. There were many small herds where no tuberculous animals, or only 1 or 2 per cent, was found. The author believes that the percentage of tuberculous cattle for the whole country is below 20.—F. W. WOLL.

Bacteriological work, F. D. CHESTER (*Delaware Sta. Rpt. 1897, pp. 38-42*).—The preparation of anthrax vaccines is briefly described, and bacteriological examinations of 12 samples to determine anthrax reported.

A study of National and of State legislation on anthrax, A. T. NEALE (*Delaware Sta. Rpt. 1897, pp. 8-19*).—Reprint of Bulletin 37 of the station (E. S. R., 10, p. 396).

On the influence of potable water of varying chemical composition upon the virulence of splenic fever bacilli, P. DROSDOWSKI (*Frach, 1898, No 3*).

Hog cholera, G. A. WATERMAN (*Michigan Sta. Bul. 157, pp. 323-328*).—A general discussion of the subject, including the cause, symptoms, treatment, disposal of the carcasses, and methods of cleaning the pens where infected animals have died. The favorable results attending the injection of serum from immune animals are mentioned.

Glanders of Dries, D. HUTCHEON (*Agr. Jour. Cape Good Hope, 13 (1898), No. 8, pp. 453-460*).—A general article, giving symptoms and treatment. Citations from the "Animal disease act" are given.

Tuberculosis in cattle and its control, J. LAW (*New York Cornell Sta. Bul. 150, pp. 30, pls. 2, figs. 3*).—A general discussion, summarizing the present knowledge of the subject. The author's experience in eradicating tuberculosis from two herds with-

out the use of tuberculin test is reported in detail. The importance of the tuberculin test is, however, insisted upon. The need of State legislation is discussed, the author believing that stock in New York are menaced by the lack of proper legislation, since herds are being infected by the introduction of cattle brought from other regions where there are strict laws upon the subject.

The appearance in the blood serum as the effect of chemical products of a substance capable of agglutinating the tuberculosis bacillus, S. ARLOING (*Compt. Rend. Acad. Sci. Paris*, 136 (1898), No. 22, pp. 1550-1555).—Experiments with goats are briefly reported.

Tuberculosis, D. McCRAE (*Rpt. Agr. New Brunswick, 1897*, pp. 243-257).—A general article on tuberculosis and the importance of the tuberculin tests, together with a discussion.

Tuberculosis in spayed cattle, W. C. QUINNELL (*Queensland Agr. Jour.*, 3 (1898), No. 4, pp. 317, 318).—The author points out the danger of infection with tuberculosis when cows are spayed. The necessary precautions are briefly pointed out. The article is based on the author's experience.

The Royal Commission on tuberculosis, J. MCFADYEAN (*Jour. Roy. Agr. Soc. England*, 3. ser., 9 (1898), Pt. II, No. 34, pp. 323-344).

The effect of smoke upon the life of tuberculosis bacilli in meat, FORSTER (*Deut. Med. Wochenschr.*, 24 (1898), No. 11, *Vercins Beilage*, No. 8, pp. 47; *abs. in Ztschr. Fleisch u. Milchhyg.*, 8 (1898), No. 10, pp. 188, 189).—Experiments on the effect of smoke and the moisture content of the air are reported.

Studies on rabies: I. Inoculation experiments with wolves, E. DI MATTEI (*Arch. Hyg.*, 33 (1898), No. 3, pp. 266-314).—A large number of experiments are reported.

Roup and rozz antitoxin (*Philadelphia, H. K. Mulford Co.*).

Gastro enteritis in cattle due to worms, MCFADYEAN (*Jour. Comp. Path. and Therap.*, 1897; *abs. in Ztschr. Fleisch u. Milchhyg.*, 9 (1898), No. 2, pp. 30, 31).

Laminitis, fever in the feet, founder, etc., D. HUTCHEON (*Agr. Jour., Cape Good Hope*, 13 (1898), No. 8, pp. 448-453).—The diseases, symptoms, and treatment are discussed.

The anaerobism of tetanus bacilli, J. FERRÁN (*Centbl. Bakt. u. Par.*, 1. Abt., 24 (1898), No. 1, pp. 28, 29).

Certain biological and animal pathogenic characteristics of Bacillus proteus, M. MEYERHOF (*Centbl. Bakt. u. Par.*, 1. Abt., 24 (1898), No. 1, pp. 18-27; 2-3, pp. 55-61; 4-5, pp. 148-154).—An extended study of the subject, with bibliography.

The nature of the antagonism between toxins and antitoxins, C. J. MARTIN and T. CHERRY (*Proc. Roy. Soc. [London]*, 63 (1898), No. 400, pp. 420-432).—A number of experiments are reported.

AGRICULTURAL ENGINEERING.

The loss of water from reservoirs by seepage and evaporation, L. G. CARPENTER (*Colorado Sta. Bul.* 15, pp. 32, fig. 1).—A record is given of observations on seepage from a series of reservoirs near Fort Collins in the winters of 1895-96 and 1896-97, and on evaporation from the reservoirs and from an evaporation tank. The results are discussed in detail and summarized as follows:

“The seepage losses may be great. In the lakes under measurement the losses in some cases were less than from evaporation alone. In some cases lakes may gain from seepage from irrigated lands, and the gain may be more than the combined loss from seepage and evaporation. In the cases where loss from seepage occurred, the loss was at the rate of about 2 ft. in depth over the area of the lake per year. This

amount does not necessarily apply to other sites, and other observations are needed before general statements respecting loss from this source can be made.

"The seepage decreases after the lake is first filled, from the effect of silting and from having filled the porous ground underneath and connected with the site. Even in sand there is a limit to the amount of seepage, and the time during which the loss is large. After sand beds connected with the reservoir are saturated the losses from seepage will decrease. The loss increases with the depth, probably nearly as the square. The losses may be lessened, though not entirely prevented, by silting. The silting process is more efficient with small reservoirs, because of the better distribution of the silt.

"If the loss from seepage is not more than 2 ft. per annum, the sites may be considered as practically water-tight. In the case of canals the losses often average more than that in 24 hours.

"The losses from evaporation in the cases examined are greater than those from seepage, and the evaporation is not necessarily the same from adjacent bodies of water. The amount of evaporation increases with the temperature of the water, with the wind, and diminishes with increased moisture in the air. From the standard evaporation tank at the experiment station, the average evaporation for 11 years has been 41 in.

"Evaporation proceeds when the water is frozen, but at a diminished rate, averaging about 1 to $1\frac{1}{2}$ in. per month. The evaporation at night is the same as during the day, the difference being less with the increase of the size of the bodies of water.

"The loss by evaporation from several lakes exceeded that from the standard tank, the loss from the lakes being about 60 in. per year. The increase is due to higher temperature of the water and to freer exposure to the wind. In some of the summer months the lakes lost twice as much as the standard tank. The lower temperature of water at high elevations, and the lower dew points, tend to decrease the evaporation.

"The diminished barometric pressure tends to increase the evaporation, amounting to 14 per cent at 8,000 ft. and to 18 per cent at 10,000 ft. over the evaporation at 5,000 ft.

"Since the winter period is longer at the high elevations, it is probable that for the whole year the evaporation is considerably less at the high elevations than at the low ones.

"Every mile of wind movement in 24 hours increases the evaporation by from 1 to 2 per cent over the evaporation if calm. Evaporation is lessened by any influence which diminishes the wind or decreases the temperature of the water. Protection of lakes by wind-breaks is in many cases practicable and in small lakes sometimes desirable. In the large lakes the benefit is by reducing the wind velocity; in small lakes both from effect on wind and by lessening action of sun.

"The deeper the lake the cooler the water as a whole, the cooler the surface, consequently the less evaporation.

"Assuming a loss of 5 ft. in depth per annum, an area of 100 acres would require $\frac{3}{4}$ cu. ft. per second for the whole year to make good the losses from evaporation; one of 500 acres would require $3\frac{1}{2}$ cu. ft. per second, considerably more than would be used to irrigate an equal area.

"The net loss to the reservoir would be the sum of the above losses from seepage and from evaporation, diminished by the rainfall, a combined loss which may be considered as a depth of 6 ft. in one year. As irrigation reservoirs are usually full for a few months only, the loss is much less than this for the high water area."

Object-lesson roads, R. STONE (*U. S. Dept. Agr. Yearbook 1897, pp. 373-382, pls. 2, fig. 1*).—This is an account of the construction of short sections of roads to serve as object lessons at New Brunswick, Florence, and Englishtown, New Jersey; Geneva and Ilion, New York; Warren, Pennsylvania, and Kingston, Rhode Island, with remarks on State aid to road building in Massachusetts, and suggestions regarding the construction of a coastwise and transcontinental highway to serve as a national object lesson.

Cold storage (*Rpt. Com. Agr. and Dairying, Canada, 1897*, pt. 5, pp. 87, figs. 50, pls. 6).—The different uses, methods, and applications of cold storage are discussed, plans are given for construction of ice house, refrigerator room, cold-storage room for a creamery, and cold-storage buildings of several kinds.

Preliminary results of trials of mowers, horse-rakes, and hay-turning machines at Stend, Norway, 1898, N. SVERDRUP (*Tidsskr. Norske Landbr.*, 5 (1898), No. 8, pp. 398-400).

STATISTICS—MISCELLANEOUS.

Ninth Annual Report of Delaware Station, 1897 (*Delaware Sta. Rpt. 1897*, pp. 232).—This contains a financial statement for the fiscal year ending June 30, 1897, a report of the director, including a review of national and State legislation on anthrax, and reports of the various departments noted elsewhere.

Yearbook of the Department of Agriculture, 1897 (*U. S. Dept. Agr. Yearbook 1897*, pp. 792, pls. 40, figs. 45).—This includes a general report by the Secretary on the operations of the Department during the year; articles setting forth the work of the several bureaus, divisions, and offices; numerous semipopular articles noted elsewhere; and an appendix containing notes on the organization of the Department, a list of the agricultural colleges and stations in the several States, a list of the Department publications for the year, data on feeding, fertilizers, and fungicides; a list of one hundred of the most valuable trees in the United States, with their characteristics and uses and their preferred environment; tables showing the number and value of farm animals, the acreage and value of the principal crops, the imports and exports of agricultural products, and transportation rates. The volume has a comprehensive index.

Agricultural production and prices, G. K. HOLMES (*U. S. Dept. Agr. Yearbook, 1897*, pp. 577-606).—By means of statistical tables and discussion the author presents a review of the development of the agricultural resources of the United States; treats of various economic questions, as tenancy, wages, production, labor, and capital in reference to agriculture; and considers the economic use of fertilizers, and prices of agricultural products, pointing out influences that depress prices, viz: "Production increasing faster than population, necessitating the meeting of cheaper foreign agricultural labor in the world's market; cheaper transportation; cheaper cost of production due to machines and improved implements; reduced expenses of marketing; the dissemination of information and the multiplying of the means and facilities of transportation, preventing scarcity with respect both to time and place, and thus steadying prices."

Visit to Great Britain and Ireland (*Rpt. Com. Agr. and Dairying, Canada, 1897*, pt. 6, pp. 32).—Among other matter this bulletin gives statistics of the amount of foods imported into Great Britain during several years.

Constitutions and by-laws for farmers' organizations J. HAMILTON (*Pennsylvania Dept. Agr. Bul.*, 36, pp. 72, dgms. 2).

Some books on agriculture and sciences related to agriculture, published 1896-1898 (*U. S. Dept. Agr., Office of Experiment Stations Circ.*, 28, pp. 45).—A bibliographical list of more than 450 publications.

Agricultural outlook for the coast region of Alaska, W. H. EVANS (*U. S. Dept. Agr. Yearbook 1897*, pp. 552-576, pls. 4).—The substance of this article has already been issued as Bulletin 48 of this Office (E. S. R., 9, p. 1097).

On the development of Swedish agricultural technical industries during the past 25 years, A. G. EKSTRAND (*K. Landt. Akad. Handl. Tidsskr.*, 37 (1898), No. 4, pp. 203-246.)

NOTES.

IOWA STATION.—C. F. Curtiss, director of the station, has been granted leave of absence for 3 months, beginning April 1, for a trip abroad to study the agricultural conditions of Great Britain and Western Europe.

KANSAS COLLEGE AND STATION.—E. E. Faville, horticulturist and entomologist in the college and station, has resigned to accept the presidency of the National Farm School at Doylestown, Pennsylvania, a new industrial institution under the auspices of a Jewish association. W. L. Hall, assistant horticulturist, and Percival J. Parrott, assistant entomologist, are temporarily in charge of the work in their respective departments. Mr. Parrott is studying scale insects in New Mexico. F. C. Burtis, assistant in feeds and feeding, has been granted leave of absence for a year to study in other agricultural colleges. His place will be taken temporarily by J. G. Haney. Geo. L. Clothier, assistant botanist, has been granted leave of absence until the first of June to study plant breeding at Cornell University. His place will be supplied by J. M. Westgate.

SOUTH CAROLINA COLLEGE AND STATION.—J. W. Hart, instructor in dairying, has resigned to accept a position in the Dairy School at Kingston, Ontario, and C. M. Conner has been assigned the duties of the dairy department in the college and station. J. V. Lewis, geologist, has resigned his connection with the station staff, in order to devote his entire time to the college.

TENNESSEE UNIVERSITY AND STATION.—Charles F. Vanderford, professor of agriculture in the university and secretary and agriculturist in the station, died January 3, 1899. Professor Vanderford had from long study become thoroughly familiar with the agriculture of his State, and for many years had been closely identified with all its agricultural interests. He was an enthusiastic student of those branches of natural science upon which agriculture is based, and during the last 30 years of his life gave his best efforts to the advancement of the farmer. He rendered valuable service in revising, correcting, and condensing a report upon tobacco, published in the Tenth Census of the United States. He was for many years president of the Tennessee Stock Breeders' Association, and from 1889 to 1891 was assistant commissioner of agriculture of the State. He had been connected with the university and station since 1891. John R. Fain has been appointed to succeed John L. Spinks as farm manager. At the last meeting of the board of trustees of the university an order was made for the establishment of a system of farmers' institutes. The experiment station staff are at work perfecting plans, and the first institutes will be held during the winter and spring.

NECROLOGY.—Dr. Carl Brunnemann, director of the agricultural institute at Itabirade-Mata-Dentro, Brazil, died October 27, 1898. Dr. Brunnemann was formerly director of the agricultural experiment station at Posen, Germany. In 1891 he was engaged by the Brazilian Government to organize an agricultural experiment station at Barbacena, in the Province of Minas-Geraes. He was quite widely known through his investigations in Minas-Geraes, and his travels. In 1894 he established the agricultural institute at Itabira.

Dr. C. G. Gibelli, professor of botany and director of the Botanic Institute of the University of Turin, died September 16, 1898.

Gilbert H. Hicks, assistant botanist of this Department, in charge of seed investigations, died December 5, 1898.

EXPERIMENT STATION RECORD,

EDITED BY

A. C. TRUE, PH. D., *Director*.

Committee of the Association of Official Agricultural Chemists.

CONTENTS OF Vol. X, No. 7.

Editorial notes:	Page.
Experiment station movement in Russia	601
Present status of the experiment stations in Russia	603
Recent work in agricultural science	605
Notes	699

SUBJECT LIST OF ABSTRACTS.

CHEMISTRY.

Methods of determining potash and the best precipitants of platinum, A. Atterberg	605
Modifications of the Kjeldahl method for determining nitrogen, A. Atterberg ..	605
Contribution to investigations on manganese in minerals, plants, and animals, P. Richard	605
The quantitative separation of hemicellulose, cellulose, and lignin, and the occurrence of pentosans in these substances, W. Hoffmeister	606
Proceedings of the fourteenth annual convention of the Association of Official Agricultural Chemists	606
Report of the chemist, J. B. Lindsey	607

BOTANY.

Experiments on the production of alpine characters in plants by the alternation of extreme temperatures, G. Bonnier	608
Half shade and vegetation, B. D. Halsted	610
Influence of carbon dioxide on the form and structure of plants, E. C. Tódoresco	610
On the poisonous effect of the salts of copper on the higher plants, H. Coupin ..	611

Medicinal plants which have been collected and used in North Carolina, C. W. Hyams	612
--	-----

METEOROLOGY—CLIMATOLOGY.

Report on the work of the station of agricultural climatology at Juvisy during 1897, C. Flammarion	613
Meteorological observations, C. S. Phelps	616
Report of the meteorologist, J. E. Ostrander	617
Meteorology, J. E. Bonebright	617

WATER—SOILS.

The conservation of soil moisture and economy in the use of irrigation water, E. W. Hilgard	617
Measurements of soil temperatures at Norwegian observation stations, 1892-1897, J. Sebelien	618
Observations on the management of sewage farms, O. Pfeiffer	618
Nitric nitrogen produced by the pea, J. L. Beeson	618
On denitrification, G. Ampola and C. Ulpiana	619

FERTILIZERS.

Experiments with ferrous sulphate for destroying the denitrifying organisms of barnyard manure and the germs of Rothlauf and Schweinesenche, O. Müller	620
On denitrifying organisms, O. Künemann	621
Comparison of different phosphates, W. P. Brooks	622
Natural phosphates compared with each other and with acid phosphate, W. P. Brooks	624
Analyses of commercial fertilizers, J. L. Hills, B. O. White, and C. H. Jones	623
Analyses of commercial fertilizers	624
Report of the chemist, department of fertilizers and fertilizer materials, C. A. Goessmann, et al	623

FIELD CROPS.

Composition of maize, H. W. Wiley	624
Report of the agriculturist, W. P. Brooks	626
Report of the director, H. Benton	628
Notes on flax and hemp, H. T. French	635
Millet, E. C. Chilcott and D. A. Saunders	629
Forage crops of the James River Valley, J. H. Shepard and E. C. Chilcott	629
Potato experiments, C. von Seelhorst	629
Sugar beets in Idaho, C. W. McCurdy	630
Sugar beets, R. H. McDowell and N. E. Wilson	631
Sugar beets, W. A. Withers	636
Sugar beets in South Carolina, M. B. Hardin and J. F. C. DuPre	631
Notes on field experiments with tobacco in Massachusetts, 1893-1896, C. A. Goessmann	636
Experiments with winter wheat, C. A. Zavitz	631
Wheat, winter oats, barley, and lime experiments, R. H. Miller and L. H. Brinkley	633
Field experiments with wheat, oats, and barley, L. A. Merrill	634
The influence of a temporary low temperature on the development of winter grains when sown in spring, C. von Seelhorst	635
On the influence of smaller and larger amounts of water on the development of some cultivated plants, A. Mayer	635

EXPERIMENT STATION RECORD.

VOL. X.

No. 7.

It is learned from a recent official report that steps are being taken in Russia for the establishment of a system of agricultural experiment stations under the supervision of the Imperial Government. The ministry of agriculture has elaborated a plan for such a system of institutions, which has been passed upon and approved by the agricultural council. In accordance with the usual course of events in that country, this action will be followed at an early date by the issue of a royal decree definitely inaugurating the system.

The plan proposed and approved provides for four classes of institutions, namely: (1) agricultural experiment stations for scientific investigation of problems in agriculture, chiefly by laboratory methods; (2) experimental fields (or orchards and gardens) for making field experiments in the culture, etc., of agricultural crops, with a view to solving technical questions of a more local character; (3) semiscientific experiment farms, for conducting practical experiments in general farm management under local conditions, studying economic questions, etc.; and (4) fields of demonstration (also orchards and gardens of the same character) for demonstrating the application in practice of the results of experiment station work, improved methods which have been tested on the experimental fields, new kinds and varieties of valuable plants, breeds of animals, farm implements, etc. Where desirable these four types of stations may be united into one institution with the several departments.

The stations may be divided again, according to the scope of their work, into (1) those which are working on the fundamental principles underlying the practice of general agriculture, and (2) those which are studying, by similar methods, questions of a more local character. Stations of the first class will be located in the vicinity of the centers of scientific learning, and those of the second class in typical agricultural regions and, where possible, near the local centers of education.

The experiment stations are to be provided with laboratories, collections, libraries, and other facilities as required by their particular lines of work. In some cases they will be provided with departments of agricultural meteorology. They will have under their direction small tracts of land (only a few acres) as required for their work. Aside from their regular investigations they will make analyses of soils, fer-

tilizers, agricultural products, etc., for private persons, according to a fixed schedule of prices.

The experimental fields will be established in regions which are typical in regard to soil, topography, and other conditions. They will have a considerable tract of suitable land (up to 160 acres), according to their special purpose, and where necessary to the work being done they will have laboratory facilities for making simple analytical determinations.

The experiment farms will correspond in general character to the farms or estates of the localities in which they are located. There may be affiliated with these farms special departments for horticulture, gardening, and agricultural technology, and also for introducing improved breeds of animals, implements and machines, distributing seeds of improved varieties, etc. The experimental fields and farms will conduct meteorological and phenological observations.

The fields of demonstration are to be established near localities which are most visited by the rural population, and preferably in connection with educational institutions.

The experiment stations will each have a director and at least two assistants. The experimental fields and farms will each have a director and at least one assistant. So far as possible these will be selected from persons who have received an education in agriculture or the natural sciences. The managers of the fields of demonstration will, where practicable, be chosen from the local residents, and will be under the supervision of a specialist. Provision is made for the formation of councils for such experiment stations as have experimental fields and farms, to be composed in each case of the director and his assistants, a representative of the ministry of agriculture, persons who have aided in establishing the station, and other persons selected by the council. The general plans for work for terms of four or five years are presented by the director to the council, and later to the minister of agriculture for his approval. The approval of the annual plan of operations is left to the council. Where there is no council the director presents his plan of work, as well as his annual report, directly to the minister of agriculture for approval.

Arrangements may be made for the holding of public lectures and courses in various branches of agriculture at the experiment stations, under the approval of the minister of agriculture.

The experiment stations, fields, farms, etc., may be established by the government, by local communities, or by private persons. Those established by communities (zemstvos), organizations, and private persons may receive pecuniary or other aid from the ministry. The experiment stations proper, owing to the complex nature and comprehensiveness of their work, will be established chiefly by the government. The establishment of experimental fields will be left mainly to local communities, as also that of fields of demonstration. The ministry of agricul-

ture, through persons commissioned for the purpose, will exercise a supervision over the work and expenditures of the institutions which receive government aid. It will also publish an annual report of the work of the stations, and periodically will give a general survey of their operations.

It will be seen that while the government plans for the establishment and maintenance of the higher-grade institutions, it looks to local communities, organizations, and public spirited persons for the establishment of fields and farms where the work is to be of a more practical and popular nature or for purposes of demonstration and is to be restricted to the study of local questions. After these more or less private institutions have been established they may receive government aid in the form of annual appropriations, chiefly for defraying the expenses of the staff of the station and purchasing books and scientific equipment, or they may be given the use of government lands, animals for breeding, seeds of improved varieties of plants, etc. They may also have the benefit of advice and information from the specialists attached to the ministry of agriculture.

The object of the institutions which the plan contemplates is a double one—that of experimental investigation on both scientific and practical questions in agriculture, and the dissemination of information among the common people by means of fields of demonstration, popular lectures, and publications. The scheme bears evidence of thorough familiarity with the history of the experiment station movements of other countries and the tendencies which have developed. In its elaboration the experience of these institutions has been profited by, and the successful features of different countries embodied. As a result, we have a comprehensive system of stations, fields, farms, etc., each class with a definite field of work and designed to serve a definite purpose in the advancement of the science and the practice of agriculture. Taken in connection with the proposed system for agricultural education, it will be seen that there is no confusion as to the work of education, investigation, application, demonstration, and the dissemination of popular information. The need for effort along each of these lines is recognized and separate provision for it is made in the schemes elaborated. When the condition of agricultural practice in Russia is considered—the primitive implements which are used, the irrational systems which are followed, and the general lack of progress as compared with that made in other countries—it can not but be apparent that the field of usefulness for institutions of the different classes contemplated is an unusually broad one, and that the movement will eventually result in great benefit to the agriculture of that country.

According to a recent Russian article on the agricultural experiment stations of that country, there are now in Russia sixty eight stations of various kinds. The first station was established in 1864 at the

Polytechnicum at Riga. No other stations were established until 1878, when the experimental fields of the Petrov Agricultural Academy at Moscow were organized. The experimental fields of the agricultural institute at Novo-Alexandria, Poland, date from the following year. From that time on there has been a steady increase in the number of stations. The earlier stations owe their existence to zemstvos, societies, and private persons. Not until 1894 did the Imperial Department of Agriculture render assistance to the enterprise. In that year it took a considerable number of stations under its patronage, and began to open new stations in various localities in Russia. Since that time the development of these institutions has been quite rapid.

The Russian stations as they exist at present may be divided into three groups, (1) stations for general investigation, conducting experiments on their own fields, of which there are 43; (2) stations for special investigations, of which there are 14—3 for silk culture, 2 for apiculture, 2 for flax culture, 2 for bacteriological investigations, 1 for dairying, 3 for viticulture, and 1 for vegetable growing; and (3) control stations, of which there are 11. Some of the stations are wholly maintained by the government, while others are supported by local communities, societies, and private persons, in some cases with the aid of the ministry of agriculture. A number of the stations receive annual appropriations amounting to \$2,800 from the government, and the Turkestan Station receives about \$3,800 from that source.

Among the best-equipped stations are said to be the Plotyansk, Derebchinsk, Zapolsk, and Poltava stations for general work, the Tiflis Station for silk culture, the Edimonov Station for special work, the control stations at Warsaw, Riga, and Helsingfors, and the St. Petersburg Bacteriological Station.

The station staff usually consists of two persons, a director and an assistant, although in some instances there are additional regular assistants as well as volunteer assistants.

Aside from the inadequate number of stations (one station to 90,000 square kilometers) and their unequal distribution, which leaves important agricultural regions without any provision for experimental work, the absence of a unifying central institution is believed to be a great hindrance to their development. There is no general plan of organization. They have no organ for the publication of their results, and information regarding them is difficult to obtain. The experiment station movement which has been inaugurated by the ministry of agriculture should remedy these conditions, add materially to the influence of the stations already existing, and bring their work into closer touch with more advanced classes of agriculturists.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

Methods of determining potash and the best precipitants of platinum, A. ATTERBERG (*Chem. Ztg.*, 22 (1898), No. 51, pp. 538, 539).—The article discusses the several methods that have been proposed for the determination of potash, in the light of experiments made by the author. The gravimetric methods are considered as a rule more satisfactory than the volumetric methods. Of the gravimetric methods the author considers that of Villiers and Borg (*E. S. R.*, 5, p. 538) the best, of the volumetric methods that of de Koninck.¹ A method for determining potash directly in solutions containing iron and aluminum is also described. After freeing the solution from silica, it is evaporated to dryness with an excess of citric acid and sufficient platinum chlorid. The citrates of iron and aluminum are then taken up with alcohol, and the potash in the residue determined in the usual way.

As the result of numerous experiments made by himself, the author concludes that magnesium, mercury, and thioacetic acid are the best precipitants of metallic platinum from platinic solutions.—J. T. ANDERSON.

Modifications of the Kjeldahl method for determining nitrogen, A. ATTERBERG (*Chem. Ztg.*, 22 (1898), No. 50, pp. 505, 506).—The author records a series of experiments which were instituted to determine the relative value of a number of oxidizing agents. He concludes that the best means of oxidation is 20 cc. of concentrated sulphuric acid with 15 to 18 gm. of potassium sulphate and some mercury. The potassium sulphate may be added in the beginning except with substances which foam, when it should be added after solution has taken place. The solution becomes clear in about 30 minutes.—J. T. ANDERSON.

Contribution to investigations on manganese in minerals, plants, and animals, P. RICHARD (*Compt. Rend. Acad. Sci. Paris*, 126 (1898), No. 26, pp. 1882-1885).—The method which the author has previously described (*E. S. R.*, 9, p. 1023) was applied to a number of soils, plants, and animal products with the result of showing the widespread distribution of manganese in nature. The hymenomycetous fungi appear to be especially rich in this substance, but other fungi and mosses are well supplied with it. Among vascular cryptogams the ferns are the most abundantly supplied. Of the gymnosperms the conifers are richest in manganese. Of the angiosperms the Gramineæ, Leguminosæ, Rosa-

¹ *Chem. Ztg.*, 20 (1896), p. 502.

ceae, Cruciferae, Umbelliferae, Ampelideae, Solanaceae, Liliaceae, Polygonaceae, and Urticaceae are rich in manganese. It is abundant in oaks, elms, hornbeam, chestnuts, and poplars. The manganese appears to be concentrated in the leaves and young shoots (the active organs of vegetation). It is found in greatest abundance, however, in the seeds of flowering plants, such as wheat, barley, oats, maize, beans, buckwheat, hemp, coffee, figs, prunes, raisins, apples, and poplar and in fleshy roots, such as the potato. Manganese is present to a much less extent in animals than in plants. The egg yolk contains much more than the white. The egg as a whole contains more manganese than flesh or bone. Horny portions of animals, and in general skin with its associated parts, contain considerable amounts of manganese.

The quantitative separation of hemicellulose, cellulose, and lignin, and the occurrence of pentosans in these substances, W. HOFFMEISTER (*Landw. Vers. Stat.*, 50 (1898), No. 5-6, pp. 317-362).—Following a discussion of the properties of these materials, the author describes their separation from sunflower-seed hulls. A large quantity of the hulls was extracted with ether, hydrochloric acid, and ammonia, and the residue was treated successively with 5 per cent sodium hydroxid (giving 2.78 per cent of hemicellulose), with Schweizer's reagent (giving 6.7 per cent of cellulose), and with hydrochloric acid and ammonia (giving 56.7 per cent of lignin). The hemicellulose contained 81.4 per cent of pentosan and the cellulose 54.5 per cent. Fifty grams of the lignin (insoluble residue) yielded, after treatment with dilute ammonia for 6 days, 1.91 gm. of hemicellulose containing 36 per cent of pentosans and 20.16 gm. of cellulose containing 2.18 per cent of pentosans. The ammoniacal extract and washings yielded 13.26 gm. of incrusting substance, and the undissolved residue of 14.21 gm. gave, on further treatment with ammonia, 2.30 gm. of cellulose. Hence the 50 gm. of lignin was found to consist of 24.37 gm. of cellulose and hemicellulose, and a residue comprised of incrusting substances and ash.

The author suggests that determinations of this sort may be of assistance in studying digestibility.

Studies were made on the effect of dilute ammonia on the cellulose bodies of lignin, and on the effect of dissolving cellulose in Schweizer's reagent on its solubility in sodium hydrate solution. Determinations are reported of the cellulose (Schweizer's extract) and lignin, and the proportions of pentosans in each of these, in clover at different stages of the first and second years of growth. These indicate an increase in both years in both the cellulose and lignin during the growing period. In the first year an absolutely as well as relatively larger amount of these substances was produced than in the second year. The amount of pentosans in the Schweizer extract was relatively higher the second year than the first, but the reverse was true for that in the lignin. All of the above results are believed to need confirmation.

Proceedings of the fourteenth annual convention of the Association of Official Agricultural Chemists (*U. S. Dept. Agr., Division of Chemistry Bul.* 51, pp.

169).—A detailed account, edited by the secretary of the association, H. W. Wiley, of the proceedings of the convention of this association, held at Washington, D. C., October 26-28, 1897, a summary account of which has already appeared (E. S. R., 9, pp. 104-114).

Progress in agricultural chemistry, W. SCHNEIDEWIND (*Chem. Ztg.*, 22 (1898), No. 82, pp. 870, 871; 85, pp. 905-907; 86, pp. 911-913).—Reviews briefly recent investigations on soils (especially the losses of fertilizing constituents from the soil), barn-yard manure, green manures, and nitrogenous commercial fertilizers; on phosphoric acid, potash, and lime; on plant and animal production, and on analytical methods for fertilizers and foods. Most of the investigations referred to have been noted from time to time in the Record.

Report of the chemist, J. B. LINDSEY (*Massachusetts Hatch Sta. Rpt.*, 1897, pp. 74-78).—Brief notes are given on the work of the chemical department, which included examination of a number of samples of water and milk, determination of starch, experiments with pigs, and a study of the feeding value of salt-marsh hay (E. S. R., 10, pp. 172-181).

Determination of phosphoric acid in superphosphates, L. VIGNON (*Bul. Soc. Chim. Paris*, 3. ser., 19 (1898), No. 20-21, pp. 860-862).—This article has already been abstracted from another source (E. S. R., 10, p. 410).

Tables for calculating phosphoric acid from magnesium pyrophosphate. GÖLTSCHKE (*Tabelle zur berechnung der pyrophosphorsäuren magnesia auf phosphorsäures Wiesbaden: C. W. Kreidel*, 1896, pp. 20).

Methods and solvents for the approximate determination of the probably available plant food in soils, W. MAXWELL (*Landw. Vers. Stat.*, 50 (1898), No. 5-6, pp. 331-334).—This article has been noted from another source (E. S. R., 10, p. 527).

Comparison of methods for estimating caffeine, E. F. LADD (*Amer. Chem. Jour.*, 20 (1898), No. 10, pp. 866-869).—The author compares the methods of Peligot, Crosshoff, and Gomberg.

Determination of tannin, L. VIGNON (*Bul. Soc. Chim. Paris*, 3. ser., 19 (1898), No. 22, pp. 923-926).

Method of determining starch in black and in white mustard seed, J. W. LLOYD (*Bul. Pharm.*, 12 (1898), No. 11, pp. 497-499).

Detection of formic aldehyde in food substances, E. RIMINI (*Ann. Farm.*, 1898, p. 97; *abs. in Bul. Soc. Chim. Paris*, 3. ser., 20 (1898), No. 23, p. 896).

The determination of dirt in milk, R. EICHLÖFF (*Ztschr. Untersuch. Nahr. u. Genussmtl.*, 1 (1898), No. 10, pp. 678-683).—Instead of Stutzer's sand filter, the author proposes to separate the foreign matter in milk by whirling samples of 300 cc. in a centrifugal run at the rate of 2,000 revolutions per minute, and to collect the sediment on an asbestos filter. Samples to be tested in this way must be perfectly sweet and, as a preservative, the author recommends potassium bicarbonate instead of formalin, as the latter is said to curdle a small part of the casein, which is then separated with the dirt.

Analysis of milk—determination of the amounts of added water, A. VILLIERS and M. BERTAULT (*Monit. Sci.*, 12 (1898), Apr., pp. 270, 271; *abs. in Jour. Soc. Chem. Ind.*, 17 (1898), No. 7, p. 686).

The value of Fleischmann's formula in milk analysis, E. ACKERMANN (*Milch Ztg.*, 27 (1898), No. 49, p. 770).—Remarks on the use of the formula in laboratory work.

Composition of the proteids of cereal and leguminous seeds: Practical results of the researches of E. Fleurent, A. LIVACHE (*Bul. Soc. Encour. Ind. Nat.*, 97 (1898), pp. 547-550; *abs. in Jour. Soc. Chem. Ind.*, 17 (1898), No. 7, p. 687).

Method for the quantitative determination of proteids in beer wort and other protein solutions, H. SCHJERNING (*Ztschr. Analyt. Chem.*, 37 (1898), No. 7, pp. 413-422; *abs. in Analyst*, 23 (1898), Dec., p. 326).—In this paper the author summarizes the results of his previous work in this line, and presents a complete method for determining the different proteids in solution.

New contributions on the determination of fat in animal tissues and fluids, J. NERKING (*Arch. Physiol.* [Pflüger], 73 (1898), No. 3-4, pp. 172-184).—The author believes the only quantitative method for determining fat in meat to be digestion with pepsin and hydrochloric acid and subsequent extraction with ether, as suggested by Dornmeyer (*E. S. R.*, 7, p. 919). He proposes to simplify the extraction by the use of a somewhat intricate apparatus, which he illustrates and describes. The results of trials of the method on various kinds of meat, milk, etc., are reported.

Contributions to the analysis of fat. III, The detection of cotton-seed oil in lard, A. BÖMER (*Ztschr. Untersuch. Nahr. u. Genussmitt.*, 1 (1898), No. 8, pp. 532-552, fig. 1).

The use of benzal in determining the iodine number of fats and the volatile portion of fatty acids, K. FARNSTEINER (*Ztschr. Untersuch. Nahr. u. Genussmitt.*, 1 (1898), No. 8, pp. 529-532).

Creatin and its separation, E. F. LADD and P. B. BOTTENFIELD (*Amer. Chem. Jour.*, 20 (1898), No. 10, pp. 869-871).

The quantitative estimation of sugar in meat and urine, E. POLENSKE (*Arch. K. Gesundheitsamte*, 14 (1898), pp. 149-154; *abs. in Ztschr. Untersuch. Nahr. u. Genussmitt.*, 1 (1898), No. 2, pp. 782-784).—The percentage of sugar in a number of samples of meat is reported, as well as the author's method of determining it.

On the detection and localization of phosphorus in animal and vegetable tissues, A. B. MACALLUM (*Proc. Roy. Soc. [London]*, 45 (1898), No. 400, pp. 467-479).

Simple method of water analysis, especially designed for the use of medical officers of health, J. C. THRESH (*London: J. & A. Churchill*, 1898, ed. 2 *ent.*, pp. 55).

A new filter flask, R. WALTHER (*Jour. Prakt. Chem., n. ser.*, 57 (1898), pp. 544, 545; *abs. in Jour. Chem. Soc. [London]*, 74 (1898), No. 432, II, p. 507, fig. 1).

A thermostat for high or varying gas pressure, D. BODINE (*Jour. Appl. Micros.*, 1 (1898), No. 11, pp. 193, 194, fig. 1).—A simple and what is claimed to be a very efficient regulator is figured and described. It is claimed to be valuable where natural gas is used as a fuel or where for any cause the gas supply fluctuates.

BOTANY.

Experiments on the production of alpine characters in plants by the alternation of extreme temperatures, G. BONNIER (*Compt. Rend. Acad. Sci. Paris*, 127 (1898), No. 6, pp. 307-312, fig. 1).—The author reports experiments with a number of plants in which he has attempted to produce alpine conditions by employing greatly reduced temperatures. The perennial plants used in the experiments were white clover, *Teucrium scorodonia*, and *Senecio jacobaea*. Among the annual plants experimented with were vetches, oats, and barley. The plan of the experiment was to grow these different plants in different exposures, the first being placed in a house, the glass front of which faced north and received only diffused light. The walls of this house were double and were filled twice a day with ice. In this way the temperature is kept at an average of 7° C. and the humidity about 90 per cent. The second lot of plants were exposed to the normal and variable conditions in the neighborhood, under which the temperature ranged from 15 to 35° and the humidity from 64 to 91 per cent. The third lot of plants were placed alternately in the ice house during the night and in the open during the day. These plants therefore had an alternation of temperature from 4 to 35°. The soil in the pots was maintained at the same degree of saturation as the others. The fourth lot of plants

were grown under the same conditions as the first, except that the spaces between the walls were filled with water instead of ice, giving an average temperature of about 16°. The different plants were planted on June 3, and by August 1 they presented markedly different aspects. All those which had received the alternate day and night temperatures were much smaller than those which had been kept at a uniformly low temperature or those grown under normal conditions. In the case of the germander the difference in growth is strikingly shown in the accompanying figure. In the fourth lot of plants, where water was

FIG. 11.—Effect of alternation of temperature on plants: 1, normal conditions; 2, constant low temperature; 3, daily variation of high and low temperature.

substituted for ice between the walls, the plants made almost normal growth. The effect of the different conditions on the growth of the plants is shown in the following table:

Effect of different temperature conditions on plant growth.

Lot.	Conditions of growth.	Germander.		Vetch.		Oats.		Senecio.	Clover.
		Average height of plant.	Average length of internode.	Average height of plant.	Average length of internode.	Average height of plant.	Average length of leaves.	Length of basal leaves.	Length of longest leaves.

3	Alternate low and normal temperature.....	10	2.2	15	3	14	5	7	10
4	Constant medium temperature.....	38	5.5	80	6	50	9	15	30

Summarizing his results, the author states that plants kept at a very low temperature during the night and in the open during the day will be greatly reduced in size, their internodes will be proportionately shortened, their leaves much smaller and thicker, and they will flower much earlier. It is further stated that by an alternation of the temperature comparable to that which is produced on higher mountainous regions, it is possible to artificially produce alpine characteristics in plants grown at low elevations.

Half shade and vegetation. B. D. HALSTED (*Proc. Amer. Assoc. Adv. Sci.*, 47 (1898), p. 115).—The author reports a number of experiments in shading various truck crops with frames of lath upon supporting stakes; the spaces between the lath equaling their width, so that half the direct rays are intercepted. In general, the shade retarded the germination of Lima beans in the first crop, but the opposite was the case with the second or midsummer planting. All root crops, such as turnips, carrots, and potatoes, had a larger leaf surface in the shade, but the roots were much smaller. The shade improved the growth of salad crops, such as lettuce, spinach, Swiss chard, etc., and celery was improved the most of all. The time of blooming was greatly retarded and the period of fruitfulness materially prolonged by shading beans, peas, eggplants, tomatoes, cucumbers, and the like. Leaves grown in the shade are usually of a deeper green color and thinner than those grown in full exposure.

A study of some wild plants was made in a wood lot and adjoining clearing. The cinnamon fern (*Osmunda cinnamomea*), was noted to have graceful, drooping leaves in the wooded land, while in the open they were nearly upright. Measurements of the thickness of the leaflets showed those in the shade to be 0.098 mm., while in the cleared land the thickness was 0.258 mm. Many other differences, such as hairiness, color of stems, etc., were noted between the shaded plants and those grown in the open.

Influence of carbon dioxid on the form and structure of plants. E. C. TÉODORESCO (*Compt. Rend. Acad. Sci. Paris*, 127 (1898), No. 6, pp. 335-338).—The author reports upon a series of experiments in growing *Lupinus albus*, *Phaseolus multiflorus*, *Pisum sativum*, and *Faba vulgaris* under bell jars in an atmosphere containing carbon dioxid greatly in excess of the normal in one case and little or no carbon dioxid in another. Comparing the development of the plants, those grown in the presence of carbon dioxid had their hypocotyl, or lower internodes, greatly shortened, but the later internodes were elongated to such an extent that the total height of the plant greatly exceeded those grown without carbon dioxid. In addition, the internodes in cross section were much larger and contained a considerably greater number of fibro-vascular bundles, the leaves were much thicker, the cells of the palisade parenchyma were considerably elongated, and the intercellular spaces more extensively developed.

On the poisonous effect of the salts of copper on the higher plants, H. COUPIN (*Compt. Rend. Acad. Sci. Paris*, 127 (1898), No. 10, pp. 400, 401).—Attention is called to the investigations of Roulin showing that the presence of 0.00416 per cent of sulphate of copper in water cultures is sufficient to destroy *Sterigmatocystis nigra*, and to the investigations of Millardet showing that the zoospores of mildew are destroyed by a solution containing 0.0000002 or 0.0000003 per cent of the same.

In the author's investigations recently germinated wheat plants were grown in water cultures containing different amounts of a number of copper salts. After a few days the plants were examined and readily showed the effect of the copper upon them. The minimum percentage of the different salts which is capable of destroying the plants is as follows: Copper bibromid, 0.004875; copper bichlorate, 0.005; copper sulphate, 0.005555; copper acetate, 0.005714, and copper nitrate, 0.006102. From these figures it is shown that there is practically little difference in the toxicity of the different copper compounds, and this the author believes is due to the copper ions.

On account of the recent recommendation that 5 to 10 per cent solutions of copper sulphates be used for the destruction of weeds, the author states that in view of the facts shown in his experiments great care should be exercised in following such directions, since the amount of copper might have an injurious effect upon wheat or other plants.

Elementary botany, G. F. ATKINSON (*New York: Henry Holt & Co., 1898*, pp. XXIII + 444, figs. 500).—This work, which is designed for use in secondary schools, follows the same lines as given in Barnes' Plant Life (E. S. R., 10, p. 416) in that the subject is treated from the standpoint of function, processes, and relationships of the plant, the main divisions given being morphology, physiology, and ecology. The book has many excellent features, not the least among them being the illustrations, most of which are new, and many produced by photographic process with excellent effect.

Particular attention is rightly given the study of the lower plants, but from the amount of space given the consideration of some groups they appear unduly exalted. Nearly as many pages are given to the consideration of the morphology of the ferns and their allies as to the consideration of the gymnosperms and the angiosperms. It seems very doubtful whether so much stress should be laid upon the recent cytological studies in secondary schools, most of which have neither apparatus nor instructors for this order of work.

Extreme measures have been taken with the scientific names of plants, although the author has not been entirely consistent in following them. It is doubtful whether anything is gained by extreme decapitalization and the use of Roman type for the technical names of plants; but if an author adopts such a plan it should be carried throughout and occasional lapses into italics avoided.

Botany at the anniversary meeting of the American Association for the Advancement of Science, E. F. SMITH (*Science*, n. ser., 8 (1898), No. 202, pp. 651-660; 203, 690-700).—Abstracts are given by the secretary of the papers presented before section F of the association at its anniversary meeting in Boston, August, 1898.

A manual of agricultural botany, A. B. FRANK, trans. by J. W. Patterson (*London: Wm. Blackwood & Sons, 1898*, pp. X + 199, figs. 133; noticed in *Amer. Nat.*, 32 (1898), No. 383, p. 883).

The organography of plants, K. GOEBEL (*Organographie der Pflanzen. Pt. 2, Special Organography. Jena: G. Fischer, 1898, ill.*).

Medicinal plants which have been collected and used in North Carolina, C. W. HYAMS (*North Carolina Sta. Bul. 150, pp. 329-405*).—The author has given a descriptive catalogue of the plants which have reputed medicinal virtues and which are either native to the State or have become naturalized there. While many of the plants named are the source of regular official preparations, there is no doubt that many which are largely collected and used have little or no value. The bulletin is not intended to indorse the medicinal value of any of the species enumerated.

A new myxomycete in New South Wales, D. McALPINE (*Proc. Linn. Soc. New South Wales, 12 (1898), No. 1, pp. 82-84*).—Notes the occurrence of *Physarum cinereum* on *Stenotaphrum americanum*, *Cynodon dactylon*, and *Kyllingia monocephala*.

The anatomical structure of the stem of beets, G. FRON (*Compt. Rend. Acad. Sci. Paris, 127 (1898), No. 10, pp. 397-400, fig. 1*).—Comparative anatomical studies are reported upon *Beta vulgaris* and *B. maritima*, biennial plants, with *B. eyela*, an annual.

Concerning the red coloration of the stomata of Picea, P. SOBÄUER (*Notizbl. Bot. Garten u. Mus., Berlin, 2 (1898), No. 16, pp. 239-246*).—The author does not agree with Hartig that the red coloration of the guard cells is due to the presence of sulphurous acid in the air. He states that the red coloration of guard cells is not confined to the spruces, but has been observed in other conifers where factory smoke and fumes could not have exerted any effect. It is stated that sulphurous acid does influence chlorophyll production and may discolor the chlorophyll grain, but the author has no evidence to show that it becomes red on such account.

The nucleus of the yeast plant, H. WÄGER (*Ann. Bot., 12 (1898), No. 48, pp. 499-544, pls. 2*).—The author states that all yeast cells contain a nuclear apparatus, which is figured and described.

Concerning the nucleolus of Spirogyra, C. VAN WISSELINGH (*Bot. Ztg., 56 (1898), No. 11-12, pp. 195-226, pl. 1*).—A contribution to the study of karyokinesis.

Structure and function of the beards on cereal grasses, B. SCHMID (*Bot. Centralbl., 76 (1898), No. 1, pp. 1-9; 2, pp. 36-41; 3, pp. 70-76; 4, pp. 118-128; 5-6, pp. 156-166; 7, pp. 212-221; 8, pp. 264-270; 9, pp. 301-307; 10, pp. 328-334, pls. 2*).

On the germination of some æcidial spores, P. NYPELS (*Ann. Soc. Belge Micros., 22 (1898), No. 2, pp. 103-111, fig. 1*).—Notes are given on the germination of the spores of *Aecidium leucospermum* and some other forms.

Vegetable physiology, G. BERTHOLD (*Untersuchungen zur Physiologie der pflanzlichen Organisation. Leipzig: Wilhelm Engelmann, 1898, pt. 1, pp. IV + 243, pl. 1*).

Reaction of protoplasm to thermal irritation, K. L. SCHAEFER (*Flora, 75 (1898), pp. 135-140*).—It is stated that between 10 and 31° C. sensitiveness increases nearly in a geometrical ratio proportional to the arithmetical increase in temperature.

Light and vegetation, D. T. MACDOUGAL (*Pop. Sci. Mo., 54 (1898), No. 22, pp. 193-201*).—A popular paper in which is shown the influence of light on growth of plants.

A remarkable increase in the size of leaves apparently due to reduction of light, W. J. BEAL (*Proc. Amer. Assoc. Adv. Sci., 47 (1898), p. 414*).—Shortly before flowering several plants of *Kalmia angustifolia* were removed from Grayling, Michigan, to the grounds of the Michigan Agricultural College, where they were planted in wet muck, and over the tops about 8 ft. above was a screen of lath and leaves of trees, which cut off at least one-half of the light during the middle of the day and a larger percentage morning and evening. The leaves of these plants were much larger than normal, the surface being fully four times that of leaves from the original habitat collected the year previous.

On seasonal variations of elevation in a branch of a horse chestnut, M. CHRISTY (*Jour. Linn. Soc. Bot. [London], 33 (1898), No. 234, pp. 501-506, pl. 1*).—Notes a seasonal variation in the elevation of a limb of a horse-chestnut tree. Observations covering nearly 4 years are reported in which there seemed to be an almost regular depression and elevation of the limb.

Metals in plants, A. CHARLIER (*Jour. Hyg.*, 23 (1898), No. 1154, pp. 523, 524).

Function of calcium salts, O. LOEW (*Bot. Centbl.*, 74 (1898), No. 8, pp. 202-205; 9-10, pp. 257-265; *abs. in Jour. Roy. Micros. Soc.* [London], 1898, No. 5, p. 578).—Although calcium may be necessary to higher plants, it is not for certain fungi and algae. It is claimed that the nucleus and chlorophyll bodies, except in their earliest states, utilize calcium in forming protein compounds. The salts of strontium have no injurious action if the plant is supplied with sufficient calcium. Fungi differ in their ability to substitute rubidium for calcium.

Concerning the origin and transformation of lecithin in plants, J. STOKLASA (*Ztschr. Physiol. Chem.*, 25 (1898), No. 5-6, pp. 398-405).—This paper treats of the exchange of lecithin and proteids in plants in the dark and lecithin formation in leaves and chlorophyll free cells.

Water movement in trees, P. WAGNER (*Natur.*, 47 (1898), No. 39, pp. 463, 464).

On the growth of rhizomes, A. RIMBACH (*Beitr. Wiss. Bot.*, 3 (1898), No. 1, pp. 177-204, figs. 10).

Contractile roots and their activity, A. RIMBACH (*Beitr. Wiss. Bot.*, 2 (1897), No. 1, pp. 1-28, pls. 2).

Some particular organs from the root of *Hedysarum coronarium* in relation to *Bacillus radicola* and *Phytophthora leguminosarum*, G. MOTTAREALE (*Atti R. Inst. Incorag. Naples*, 4. ser., 11 (1898), No. 4, pp. 7).

Nitragin, A. P. AITKEN (*Trans. Highland and Agr. Soc. Scotland*, 5. ser., 9 (1897), pp. 188-195).—The author gives a popular review of the subject of assimilation of atmospheric nitrogen by bacteria and calls attention to the use of pure cultures of *Bacillus radicola*, which is supplied to the trade under the name of Nitragin. The preparation and use of this pure culture have already been referred to in this publication (E. S. R., 7, p. 906).

Low temperatures for physiological experimentation, H. B. HUMPHREY (*Jour. Appl. Micros.*, 1 (1898), No. 11, pp. 192, 193).—Describes simple methods for securing low temperatures for physiological experiments.

Concerning the pathogenesis of saprophytic micro-organisms, H. VINCENT (*Ann. Inst. Pasteur*, 12 (1898), No. 12, pp. 785-798).

Variation in the lower fungi due to medium, M. J. RAY (*Variations de champignons inférieurs sous l'influence du milieu*. Lille: Le Bigot Frères, 1898; *abs. in Jour. Hyg.*, 23 (1898), No. 1156, pp. 550, 551).

Plant forms arising through bud variation, L. BEISSNER (*Sitzber. Niederrhein. Gesell.* Bonn: 1898, p. 13).

METEOROLOGY—CLIMATOLOGY.

Report on the work of the station of agricultural climatology at Juvisy during 1897, C. FLAMMARION (*Bul. Min. Agr.* [France], 17 (1898), No. 4, pp. 775-811, figs. 16).—The work of the year, which was largely a continuation of the work of previous years (E. S. R., 8, p. 26; 10, p. 103), included investigations and observations on the relation of the sun to nature, solar rays and the growth of plants, effect of different rays of light on the color of plants, temperature of the air and soil, photography of clouds, solar radiation, rainfall, underground water, and miscellaneous experiments on plants.

Under the head of the relation of the sun to nature, the author records phenological observations at Paris and at Juvisy, including a record of the time of leafing and flowering of chestnut trees during a series of years and the return of migratory birds. An attempt is made to trace a relation between these recurrent phenomena and the activity of the

sun as indicated by the extent of sun spots on its surface. From the data thus secured the author concludes that the sun sends more heat to the earth during those periods when sun spots are most numerous, and that during such periods the seasons are more advanced and the growth of plants more vigorous.

The author continued during 1897 his experiments of previous years on the influence of different rays of the sun on the growth of plants, the principal modification of the previous experiments being the growing of plants of different kinds under light of varying intensity. As a rule the results in these experiments with sensitive plants, strobilanthus, coleus, grapes, corn, cosmos, salvia, etc., confirm those of the previous experiments. In order to determine whether plants which naturally grow best in a subdued light would give different results, experiments were made with ferns, but these behaved in every respect like the other plants experimented with. The principal results obtained in these experiments are summarized in the following table:

Growth of plants in different colored light.

	Sensi- tive plants.	Co- leus a.	Co- leus b.	Salvia.	Cos mos.	Spira.	Strobi- lan- thus.	Cab- bage.
	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>	<i>Cm.</i>
Height June 15:								
Red light	2.5	12.0	18.0	30.5	30.0	3.5	12.0	5.0
White light	2.5	12.0	15.0	30.0	30.0	3.0	12.0	5.0
Green light	2.5	12.0	18.0	30.5	30.0	3.0	14.0	5.0
Blue light	2.5	12.0	22.0	30.0	30.0	3.0	13.0	5.0
Height July 23:								
Red light	16.0	40.0	50.0	85.0	80.0	20.0	27.0	10.0
White light	6.0	30.0	30.0	70.0	70.0	14.0	19.0	6.0
Green light	4.0	18.0	18.0	38.0	50.0	3.0	16.0	5.0
Blue light	2.5	14.0	24.0	30.0	30.0	3.0	14.0	5.0
Height August 25:								
Red light	22.0	65.0	70.0	150.0	150.0	50.0	55.0
White light	8.0	40.0	32.0	150.0	150.0	40.0	25.0
Green light	6.0	20.0	24.0	60.0	60.0	12.0	28.0
Blue light	2.5	18.0	24.0	30.0	30.0	10.0	17.0
Maximum growth:								
Red light	19.5	53.0	52.0	119.5	12.0	46.5	43.0	5.0
White light	5.5	28.0	17.0	129.5	12.0	37.0	13.0	1.0
Green light	3.5	8.0	6.0	29.5	30.0	9.0	14.0	0.0
Blue light	0.0	4.0	2.0	0.0	0.0	7.0	4.0	0.0

This table shows that as a rule the greatest growth was made in the red light.

The results of experiments with sensitive plants grown in light of different degrees of intensity showed that a slightly diffused light was the most favorable. With strobilanthus and coleus intensities of 65 and 50 per cent, respectively, were most favorable to the growth of the vegetative organs. The behavior in this respect differed widely with the species of plant under trial. It is hoped by further experiments to classify plants with reference to their sensitiveness to the action of light, and thus to determine those plants which will be profitably benefited by shading. For shading plants the author recommends a cloth of loose texture. This not only insures the diffused light most favorable to the growth of many plants, but affords a protection against

cold and excessive heat and retards the evaporation of moisture from the soil.

Experiments on the influence of different solar rays on the color of plants were continued with the same plants experimented with in previous years (E. S. R., 10, p. 112), and with other species in addition. It was found that the different colored rays had different effects, both on the coloration of the plants and on the odor. As a rule plants grown in red light were much more fragrant than those grown in other colored rays. This was quite marked in the case of crassula, which when grown in the open air was almost without fragrance, but when grown in red light developed a delicate perfume resembling that of the banana or amyl acetate.

Studies of the coloration of the different plants indicated that this is almost always a chemical phenomenon. The coloring matter of the plants was extracted with alcohol and the solution tested with hydrochloric acid, ammonia, alum, etc. The results obtained are given in the following table:

The colors of different flowers and their behavior with chemical reagents.

	Color of flowers—		Color of untreated alcoholic solution.	Color of alcoholic solution treated—		
	At beginning of blooming.	At end of blooming.		With hydrochloric acid.	With ammonia.	With alum.
Mallow.....	Rose....	Pale blue.	Rose.....	Deep rose....	Greenish yellow...	Mauve.
Rose geranium.....	do....	Red.....	do.....	do.....	do.....	do.....
Verbena.....	Red....	White....	Pale rose..	Orange red..	Green.....	Pale yellow.
Hydrangea.....	Green..	Rose....	Rose.....	Red.....	do.....	Blue.
Crassula.....	White..	Red.....	Red.....	do.....	Greenish yellow....	Mauve.

The author concludes that the action of light on the plant sets free a certain amount of acid which acts on the leucites, producing a red coloration. An illustration of the possibility of modifying the color of plants is afforded by the case of hydrangea, the flowers of which are greenish yellow when they first appear and become rose colored under the action of light. In order to obtain blue hydrangea flowers gardeners are accustomed to water the plants with a solution of alum. It is very probable that the double sulphate of aluminum and potassium neutralizes the acid and converts the red color into blue.

A record is given of the temperatures recorded by a standard thermometer and by maximum and minimum thermometers. These data are discussed at some length.

The author concludes that there is no relation between the phases of the moon and the character of the weather.

In pursuance of a systematic plan for studying the relation between clouds and various atmospheric phenomena the author has made a series of cloud photographs, the method pursued in this work being described at some length.

A series of observations on the temperature of bare and sod land at the surface and at depths of from 0.05 to 1 meter are recorded. The curves of temperature show fluctuations identical in kind but varying in degree for the two kinds of soil. The variations are especially noticeable in the upper layers of soil, the sod land being warmer in winter and colder in summer than the bare soil.

A record is given of observations on solar radiation with a new form of actinometer. This instrument consists of a dark blue spherical glass reservoir containing ethyl alcohol into which extends the tapering point of a graduated tube, the upper portion of which carries a bulb. When this apparatus is exposed to the sun the reservoir is heated and the alcohol distils over into the graduated tube where it can be measured. This furnishes a basis for the calculation of the calorific power of the sun. Various improvements in the details of this apparatus and corrections which must be applied to the results obtained with it are noted. A diagram is given which compares the theoretical and actual hours of sunshine at Juvisy.

Observations on rainfall during the year are reported and the results are compared with similar observations for a long period of years. Observations on cloudiness are also reported in this connection. The rainfall observations show that precipitation has gradually increased at Paris since 1733.

As in previous years observations were made on the temperature of the water in 2 wells 13.56 and 14.08 meters deep, respectively. The temperature in the former was 11.5° C., and in the latter 11.1° .

By keeping oak trees in a uniform temperature throughout the year the author succeeded in causing the production of new leaves before the shedding of the old ones.

Meteorological observations, C. S. PHELPS (*Connecticut Storrs Sta. Rpt. 1897, pp. 252-251*).—This is a monthly summary of observations at the station during 1897 on atmospheric pressure, temperature, precipitation, cloudiness, and wind movement, and on rainfall at 21 different places in the State during May to October. The mean pressure during the year was 30.05 in.; the mean temperature, 47° F.; the precipitation, 53.03 in.; number of rainy days 116, fair days 130, cloudy days 125; total movement of wind, 76,634 miles. The length of the growing season (from the last killing frost in spring to the first in autumn) was 159 days. The meteorological conditions of the season were about normal, except in the case of precipitation, which was considerably above the average for the State (48.5 in.).

The causes of rain, J. R. PLUMANDON (*Pop. Sci. Mo., 54 (1898), No. 1, pp. 89-96*).—This is a translation from *Ciel et Terre* in which the influence of variations in temperature and moisture and the presence of dust on the production of rain is discussed.

Sunshine and cloudiness in Nebraska, G. D. SWEZEY (*Rpt. Nebraska State Hort. Soc., 27 (1896), pp. 45-47, figs. 2*).—A brief summary of observations with a description of an electrical sunshine recorder.

Report of the meteorologist, J. E. OSTRANDER (*Massachusetts Hatch Sta. Rpt. 1897*, pp. 45, 46).—A brief statement of the work of the year in the meteorological department of the station.

Meteorology, P. BÔNAME (*Rap. Ann. Sta. Agron. [Mauritius], (1897)*, pp. 1-7).—A record is given of observations on atmospheric pressure, temperature, and precipitation during the year 1897.

The meteorology of 1896 (*Trans. Highland and Agr. Soc. Scotland, 5, ser., 9 (1896)*, pp. 363-371).—Notes on the weather, summaries of observations of atmospheric pressure, temperature, sunshine, etc., during each month, with departures from normals. The influence of the season upon the character of the crops of wheat, barley, oats, potatoes, and turnips, is also noted.

Results of meteorological observations, 1894-95 (*Ergebnisse der meteorologischen Beobachtungen im Jahre 1894-95. 14-15 Ber. meteorologische commission. Naturf. Ver. Brünn. 1896-97*).

Meteorology, J. E. BONEBRIGT (*Idaho Sta. Bul. 13, pp. 76-88*).—Monthly and yearly summaries are given of the records at Moscow for 1894, 1895, 1896, and 1897; at Grangeville for 1894, 1895, and 1896; and at Nampa for 1891, 1895, and 1897. Observations are recorded on temperature, precipitation, atmospheric pressure, cloudiness, dates of first and last killing frosts, and relative humidity and mean dew-point of the growing season.

WATER—SOILS.

The conservation of soil moisture and economy in the use of irrigation water, E. W. HILGARD (*California Sta. Bul. 121, pp. 12, pls. 3, fig. 1*).—Reference is made in this bulletin to a series of soil moisture determinations which the station has undertaken with a view to utilizing "the present unusual season [1898] for the study of the limits of endurance of drought on the part of the several crop plants and with it to determine the minimum of water that will suffice for their satisfactory growth in the several soils." This work is not yet completed, but has already given some valuable results.

It has been shown that plants send down their roots to a much greater depth in the deep uniform soils of the arid region than is usual in the soils of humid regions. This is believed to be the main cause of the remarkable resistance to drought shown by plants in these regions. The author discusses the advantages of so applying the irrigation water and fertilizing that plants will be encouraged to send their roots into the depths of the soil, and of so cultivating the soil that its storage capacity will be increased and evaporation decreased.

Some of the more important conclusions are, in brief, as follows:

"The most economical mode of using irrigation water is to put it 'where it will do the most good,' close to the stem of the plant or trunk of the tree, and let it soak downward so as to form a moist path for the roots to follow to the greatest possible depth. . . . Fall plowing wherever the land is not naturally adequately absorbent and is not thereby rendered liable to washing away is a very effectual mode of utilizing the winter's moisture to the utmost. . . . Moistening the ground to a considerable depth by winter irrigation is a very effective mode of promoting deep rooting, and will thus stand in lieu of later irrigations, which, being more scant, tend to keep the roots near the surface. . . . It can not be too strongly insisted upon that in our arid climate farmers should make themselves most thoroughly acquainted

with their subsoil down to a depth of at least 4, but preferably 6 or 8 ft. . . . Similarly, no irrigator should be ignorant of the time or amount of water it takes to wet his soil to a certain depth. . . . A definite knowledge of the rapidity with which irrigation water penetrates downward and sideways in his soil should form a part of the mental equipment of every irrigator, particularly in arranging his head ditches. . . . Supposing the moisture to have reached the depths of the soil, whether from rains or from irrigation, it is essential that proper means be employed for retaining it in the land, and especially to prevent evaporation. That this is best accomplished by a mulch on the surface, and that the best mulch for the purpose, which need not be hauled on or off and is always ready, is a surface layer of loose, well-tilled soil, is now pretty well understood by all. . . . In the East, where this principle is well understood, it is considered that a surface layer 3 in. in thickness is sufficient to afford effective protection. But what is adequate in the region of summer rains is quite insufficient in California and in the arid region generally. It takes fully twice the thickness mentioned, and preferably more, to afford protection against the drought and heat lasting 5 or 6 months at a stretch."

Determinations of moisture in the soil of apricot orchards lying side by side, one cultivated and giving a good crop of fruit and growth of wood and the other uncultivated and producing poor fruit and little growth of wood, showed 244 lbs. more water per acre to a depth of 6 ft. in the former than in the latter in July.

Measurements of soil temperatures at Norwegian observation stations, 1892-1897, J. SEBELIEN (*Tidsskr. Norske Landbr.*, 5 (1898), No. 7, pp. 295-318).—The observations here recorded and discussed were begun in 1892. A report of the first year's work at Aas and Jönsberg has already been noted (*E. S. R.*, 6, p. 199). The stations at Rotvold and Bodö (the former near Drontheim, both in Northern Norway) were added in 1895. The soil at Aas and Rotvold is clayey, at Bodö sandy, and at Jönsberg, black pulverized alum slate. Observations were taken at depths of 0.25, 0.5, and 1 meter, and (in case of Aas since July, 1895) at 1.5 meters. The observations at Aas Agricultural College are particularly complete and instructive, covering a period of 5 years.

Mechanical and partial chemical analyses of the soil at the various depths are given in case of each station, and the bearing of the results on the temperature of the soil are discussed at some length.—F. W. WOLL.

Observations on the management of sewage farms, O. PFEIFFER (*Chem. Ztg.*, 22 (1898), No. 56, p. 560).—A brief discussion of the amount of fertilizing constituents absorbed from sewage by soils and the amount escaping in the drainage water, based mainly upon observations made on the sewage fields of Magdeburg. It was found that the potash was largely and the phosphoric acid completely absorbed. The drainage water, however, contained a large amount of nitrates and little organic nitrogen, thus indicating quite complete nitrification and showing the danger of loss of considerable amounts of nitrogen when the ground is not covered with crops to utilize the nitrates.

Nitric nitrogen produced by the pea, J. L. BEESON (*Jour. Amer. Chem. Soc.*, 20 (1898), No. 10, pp. 793-795).—Small plats of very fertile

bottom land of uniform character were planted in peas, peas and corn, corn, cotton, and sorghum, and one plat was cultivated like the others but kept free from vegetation. Determinations of nitric nitrogen in the soil of the different plats were made September 30, after about 6 weeks of dry weather, by the following method: "One kilogram of soil was taken about 1 ft. from the plants, in several places, but toward the center of each plat. It was shaken for 6 hours with 1 liter of water, the suspended clay precipitated with 5 gm. of sodium chlorid, one-half liter decanted, evaporated to small bulk, and the nitric nitrogen estimated in duplicate by the Tiemann and Schulze method."

The number of milligrams of nitric nitrogen in 1 kg. of soil is given for each plat below:

<i>Nitric nitrogen in 1 kilogram of soil.</i>		Mgms.
Fallow plat.....		1.010
Plat planted in peas, growing, pods nearly grown.....		3.333
Plat planted in peas, growing, pods about ripe.....		8.670
Plat planted in peas, grown and dead about two or three weeks.....		10.510
Plat planted in corn (hard), peas same as above.....		7.563
Plat planted in corn (hard).....		.310
Plat planted in cotton, growing.....		.423
Plat planted in sorghum, growing.....		.333

The data show a much greater accumulation of nitrates in the soil under leguminous plants than in the bare soil or that under corn, cotton, or sorghum. The results indicate "that the micro-organisms of the pea roots assimilate more nitrogen than the plant needs for its growth." If this be true, "peas planted with a crop would tend to increase the yield of that crop, unless the peas be so thick as to interfere with the crop's root development, or use up too much water in their growth."

On denitrification, G. AMPOLA and C. ULPIANA (*Gaz. Chim. Ital.*, 28 (1898), No. 110; *abs. in Chem. Ztg.*, 22 (1898), No. 85, p. 261).—The authors isolated from soil a denitrifying organism which differs in character from the *Bacterium denitrificans agilis* of Ampola and Garino, as well as from those of Burri and Stutzer, and Schirokikh. This organism grows well both in presence and absence of air. The name *B. denitrificans V* has been adopted by the authors for this organism, and its behavior in different media is described. The second organism was isolated from a nitrate solution which had been exposed to the air in the laboratory for some time and was undergoing decomposition with the escape of nitrogen. To this organism the authors give the name *B. denitrificans VI*. The conditions most favorable to the development of both of the organisms are a 0.3 per cent nitrate solution, and a temperature between 30 and 40° C. Sunlight has no effect upon them. In pure distilled water the organisms are capable of surviving for 7 months. When dried, *B. denitrificans V* died within 8 weeks, and *B. denitrificans VI* was alive and active at the end of 5 months.

The mechanical composition of wind deposits, J. A. UDDEN (*Augustana Libr. Pubs.*, No. 1, pp. 69).—This is a contribution to this subject from the Augustana College and Theological Seminary at Rock Island, Illinois.

“Samples of different kinds of materials moved by the wind have been collected from different places of deposition [including points in Massachusetts, Illinois, Indiana, Kansas, Nebraska, and North Dakota], and from the atmosphere directly for this study. Each of these has been separated into grades of different coarseness and the percentage of the weight for each grade in each sample has been determined. It appears that all of these samples, and presumably the greater part of such materials as owe their present position and arrangement to the action of the atmosphere, may be referred to some one of four categories. These may be characterized as (1) lag gravels, or coarse residual deposits in the rear of sand dunes; (2) drifting sand, constituting the familiar dunes in dry and sandy regions; (3) fine sand, which is soon dropped by the wind in the lee of drifting dunes; and (4) dust, which only slowly settles out of the air far away from the place where it was raised.

“Numerous observations on known eolian deposits in the field and on the mode of action of the wind have also been made to supplement this special study of the mechanical composition of wind sediments, and these are drawn upon in the discussion of the other data.”

Observations on soil moisture, R. A. EMERSON (*Rpt. Nebraska State Hort. Soc.*, 27 (1896), pp. 179-185, figs. 4).—This article records observations on cultivated v. seeded orchards; garden soil cultivated, uncultivated, mulched, in grass; mulched v. cultivated soil in potatoes; fall-plowed, spring-plowed, and unplowed soil; and wind-breaks of forest trees and hedges.

On certain soils rich in potash, A. BORNTREAGER and G. PARIS (*Landw. Vers. Stat.*, 50 (1898), No. 5-6, pp. 343-345).—This article briefly summarizes the investigations of Casoria¹ on the solubility of potash of soils of volcanic origin in acetic acid, hydrochloric acid (1.12 sp. gr.), and hydrofluoric acid applied successively; and reports results of analyses by the authors of the hydrochloric acid extract (boiling 1.12 sp. gr. with acid for 5 hours) of 4 soils of volcanic origin (from the vicinity of Vesuvius). The potash soluble in hydrochloric acid ranged from 2.71 to 5.05 per cent.

Soil bacteria which liberate nitrogen, CARON (*Die Stickstoffbildenden Bodenbakterien. Hannover: Gohmann'sche Buchdruckerei, 1897*).—Such organisms are stated to be most abundant in fallow land, less abundant under leafy plants, and least abundant under cereals.

The denitrification processes, T. PFEIFFER and O. LEMMERMANN (*Landw. Vers. Stat.*, 50 (1898), No. 1-2, pp. 115-142).—This is a detailed account of investigations already noted (E. S. R., 9, p. 536).

FERTILIZERS.

Experiments with ferrous sulphate for destroying the denitrifying organisms of barnyard manure and the germs of Rothlauf and Schweineseuche, O. MÜLLER (*Jour. Landw.*, 46 (1898), No. 2, pp. 207-232).—In culture experiments with *Bacterium denitrificans*, *B. pyocyaneus*, and *B. fluorescens liquefaciens* in bouillon containing 0.1 per cent of nitrate, ferrous sulphate was used in the form of powder at rates of from 0.2 to 5 per cent. The results show that the addition of 1 gm. of the powdered sulphate to each 10 gm. of the slightly alkaline culture solution killed all of the germs in 24 hours. In neutral solutions a smaller quantity was effective.

Two series of experiments were carried out with the same prepara-

¹ Riv. Ital. Sci. Nat., 1 (1885), No. 1. Idrol. e Climat. Med., 7 (1885), No. 9; 9 (1887), No. 3; 11 (1889), No. 8. An. R. Senola Sup. Agr. Portici, 4 (1884), No. 1; 5 (1885), No. 1.

tion on horse manure. In one series the manure contained from 80 to 82 per cent of moisture, in the other from 65 to 68 per cent. To each 100 gm. of the manure well supplied with denitrifying organisms from 5 to 25 gm. of the powdered sulphate was added, the powder being intimately mixed with the manure. From time to time nitrate bouillon was inoculated with particles of the manure. The culture experiments indicated that in order to destroy the denitrifying organisms it was necessary to mix at least 5 per cent of the powdered sulphate with the manure, provided the manure contained at least 65 to 70 per cent of moisture. When the amount of sulphate was increased to 20 to 25 per cent all organisms in the manure were killed. As a rule the sulphate was more effective in moist than in dry manure.

Another series of experiments was carried out with moist (80 per cent of water) and dry (65 to 68 per cent of water) manure in layers 1, 2, and 4 cm. thick, the sulphate being spread over the surface of the manure in layers from 1 to 2 mm. thick. The time required for the powder to be absorbed by the manure and for the organisms to be killed depended upon the thickness of the layer of the manure and the amount of moisture present. In the thin layers the organisms were completely destroyed in 24 hours, while in the thick dry layers they were still active at the end of 12 days. It appeared that in the case of the moist manure 10 per cent of the powdered sulphate was sufficient to insure complete destruction of the denitrifying organisms, while in the case of the dry manure 15 per cent was necessary.

In a third series of experiments 100 gm. portions of manure were treated with 2.5, 5, and 10 per cent solutions of the preservative. In this case 40 gm. of 5 per cent solution (2 gm. of the sulphate) was sufficient to destroy the organisms in 100 gm. of manure both in the dry and moist condition.

Culture experiments similar to those with the denitrifying organisms were made with the germs of Rothlauf and Schweineseuche. These experiments indicated that 0.44 to 0.5 per cent of the sulphate was sufficient to kill these organisms.

Two sprinklings with a 5 per cent solution of sulphate is believed to be the most practicable and effective means of destroying both denitrifying organisms and disease germs in manure.

An analysis of the sulphate used is given which shows that it contained 66.18 per cent of ferrous sulphate, 5.4 per cent of free sulphuric acid (SO_3), 5.3 per cent of ferric sulphate, and 1.32 per cent of water and insoluble residue.

On denitrifying organisms, O. KÜNNEMANN (*Landw. Vers. Stat.*, 50 (1898), No. 1-2 pp. 65-113).—The author reviews the literature of the subject, and reports in detail experiments in preparing pure cultures of denitrifying organisms from horse and cattle manure, from straw, and from different kinds of soils. The organisms isolated are described, and their behavior in different culture media and in the presence of

varying amounts of oxygen (air), nitrate, caustic lime, and sulphuric acid is discussed.

It was found that horse manure as a rule contains denitrifying organisms and these are usually of two kinds, one of them being also found in straw. The organism found only in the manure reduces nitrates in symbiosis with *Bacterium coli* and is identical with *Bacillus denitrificans* I of Burri and Stutzer. The organism found both in the manure and in straw is considered a variety of the *Bacillus denitrificans* II isolated from straw by Burri and Stutzer.

Denitrifying organisms are not present as a rule in cattle manure. Those obtained from this source were identical with *Bacillus denitrificans* I of Burri and Stutzer.

The reduction of nitrates due to the action of these organisms is considerable, but decreases with the amount of organic matter in the culture medium. *Bacillus denitrificans* I (in symbiosis with *Bacterium coli*) completely reduced the nitrate in nutrient bouillon containing as much as 0.7 per cent of that substance. *Bacillus denitrificans* II did the same in bouillon containing as high as 0.8 per cent of nitrate.

The exclusion of air as well as its free admission checked the denitrifying action of *Bacillus denitrificans* I, but were without effect upon the action of *Bacillus denitrificans* II.

Sulphuric acid is extremely active in preventing denitrification, 0.17 per cent in the culture medium being sufficient to prevent the development of the denitrifying organisms.

Denitrifying organisms are less frequently present in cultivated soils than in manure and are usually of a different kind. The denitrifying organisms isolated from soils were *Bacillus pyocyaneus*, *B. fluorescens liquefaciens*, and *B. denitrificans* III, an organism not previously described. These organisms reduce nitrates as actively as those present in manure. As in the case of the latter, the presence of sulphuric acid to the extent of 0.17 per cent completely checked the activity of the soil organisms.

Comparison of different phosphates, W. P. BROOKS (*Massachusetts Hatch Sta. Rpt. 1897, pp. 16-19*).—This is an account of experiments during 1897 on 13 eighth-acre plats planted to corn. The whole area had received an application of 600 lbs. of ground bone and 200 lbs. of muriate of potash per acre in 1896, before the laying out of the plats. In 1897 each of the plats received a basal fertilizer of potash-magnesia sulphate 50 lbs., nitrate of soda 30½ lbs., and sulphate of potash 12½ lbs. per plat. In addition to this basal fertilizer the different plats received phosphoric acid in the form of hoof meal, bone meal, dissolved boneblack, acid phosphate, Navassa phosphate, South Carolina rock phosphate, Florida soft phosphate, apatite, and basic slag.

“ [The results show] that the yield on the plats to which phosphates were applied varied without apparent relation to the availability of the phosphoric acid in the materials used. . . . The unfavorable influence of the season and possible differences in natural fertility of the soil serve to obscure the action of the phosphates employed.”

Analyses of commercial fertilizers, J. L. HILLS, B. O. WHITE, and C. H. JONES (*Vermont Sta. Buls.* 63, pp. 17-60; 64, pp. 63-76; 65, pp. 79-121).—These bulletins report analyses and valuations of 126 brands of fertilizers inspected during the spring of 1898, with notes on valuation and a discussion of the results of inspection.

“Three-quarters of the total number [of fertilizers inspected] were above guarantee in every respect, nine-tenths were essentially equal to or better than guarantee, and all afforded the commercial equivalent of their guarantees. Thirteen brands fell short more than 0.20 per cent in one ingredient, and two were lacking in two ingredients. In neither case were both ingredients seriously deficient.

“The application of pepsin digestion and alkaline-permanganate distillation methods to the several brands indicated that the quality of the organic nitrogen of about a dozen brands, notably the output of two concerns, was somewhat questionable.

“One hundred and five brands were guaranteed (directly or inferentially) to contain potash as sulphate, a claim which was verified in but 19 cases.

“The average valuation was found to be \$17.15 and the average selling price \$29.04. Two dollars out of every five invested in fertilizers paid for costs of manufacture and sale. A dollar spent for average low-priced goods (below \$28) bought 58 cts. worth of plant food; a dollar invested in average medium grade-brands (\$28 to \$32), 60 cts. worth; and a dollar paid out for average high-priced goods (\$32.50 and upwards), 67 cts. worth. A dollar bought 79 cts. worth of plant food in one brand and but 39 cts. worth in another. A fifth of the entire number of brands sold furnished less than 55 cts. worth of plant food for a dollar.

“The average composition of the goods has not varied materially from that of last year. Selling prices are the same, plant food in mixed goods is as cheap as it ever was, but owing to the low prices of raw materials the practice of home-mixing is proportionately more profitable now than hitherto.

“Home-mixtures made in this State furnished from 30 to 50 per cent more plant food at the same cost than did average manufacturers' mixtures.”

Report of the chemist. Department of fertilizers and fertilizer materials, C. A. GOESSMANN ET AL. (*Massachusetts Hatch Sta. Rpt.* 1897, pp. 106-127).—A brief summary is given of the work during 1897, including statements regarding the inspection of fertilizers and analyses of barnyard manure, wood ashes, cotton-seed meal, Damara Land guano, crematory ashes, and wool washings, with brief notes on their value as fertilizers.

Fertilizing value and statistics of production, imports and exports of oil cakes of France, MAIZIÈRES (*L'Engrais*, 13 (1898), No. 51, pp. 1235-1237).

Manure pits and cisterns, M. RINGELMANN (*Jour. Agr. Prat.*, 62 (1898), II, No. 46, pp. 707-712, figs. 7; 50, pp. 856-860, figs. 6).—A variety of pits and cisterns are described and figured.

The turning under of straw, stubble, etc., P. BONAUME (*Rap. Ann. Sta. Agron. [Mauritius]*, 1897, pp. 55-57).—The merits of this practice are discussed, the conclusion being drawn that, although it has some disadvantages, the benefits resulting from it in the improvement of the soil more than counterbalance these objections. Comparative tests of burning and turning under were made on sugar cane with results decidedly favoring the latter practice.

Fertilizer experiments with potash salts (*L'Engrais*, 13 (1898), No. 51, pp. 1241, 1242).—An account is given of experiments with wheat on calcareous, clayey-calcareous, and sandy soils, which indicate that in every case applications of potash were profitable when they did not exceed 150 kg. of chlorid or sulphate per hectare.

Nitrate of soda and the exhaustion of the soil, L. GRANDEAU (*Jour. Agr. Prat.*, 62 (1898), II, No. 40, pp. 485-487).—A popular article.

The nitrate of soda industry, MAIZIÈRES (*L'Engrais*, 13 (1898), No. 40, pp. 947, 948).

Fields for experiment and demonstration, MAIZIÈRES (*L'Engrais*, 13 (1898), No. 42, pp. 996, 997).—A popular article, based largely on the work of Grandeau, Weitz,

and Steiger, recommending field tests for determining the fertilizer requirements of soils and describing methods of conducting such tests.

Analyses of commercial fertilizers (*South Carolina Sta. Bul. 35, pp. 32*).—This bulletin gives notes on valuation of fertilizers in South Carolina and laws and regulations controlling fertilizer inspection in that State, with tabulated analyses and valuations of 112 samples of fertilizing materials inspected during the season of 1897-98.

Natural phosphates compared with each other and with acid phosphate. W. P. BROOKS (*Massachusetts Hatch Sta. Rpt. 1897, pp. 14-16*)—This is a continuation of experiments begun in 1890 (*E. S. R., 9, p. 337*). The crop grown during 1897 was Swedish turnips. The peculiarities of the season rendered the results of the experiment inconclusive.

FIELD CROPS.

Composition of maize. H. W. WILEY (*U. S. Dept. Agr., Division of Chemistry Bul. 50, pp. 31*).—This bulletin, which is compiled chiefly from the records of the Division of Chemistry, treats of the composition of Indian corn, the composition and properties of the stalks, composition of cobs, manufacture of starch, glucose, whiskey, and alcohol, and the by-products obtained in their manufacture.

The composition of maize, as shown by analyses in the United States and other countries, is discussed at length. Many analyses are quoted.

"A study of all the analyses which have been made in this division reveals the fact that maize is one of the most invariable of the cereals, maintaining under the most different climatic conditions a most remarkable uniformity of composition, and varying chiefly in the size, color, and general physical characteristics of its kernels rather than in their composition."

The fact that, as shown by analyses, American maize contains less water than European maize is also pointed out.

The high nutritive value of maize meal is insisted upon. The different processes of milling are described. Indian-corn flour is discussed at some length. In milling, the outer envelope and germ are removed. This flour has the following percentage composition: Moisture 12.57 per cent, proteids 7.13 per cent, ether extracts 1.33 per cent, carbohydrates 78.36 per cent, crude fiber 0.87 per cent, and ash 0.61 per cent. The heat of combustion as calculated is 3,836.8 calories per pound, and as determined 3,888.3 calories.

An extended study of the composition and properties of cornstalks is reported. It was found that the nodes formed 26.08 per cent of the stalk, the pith of the internodes 20.25 per cent, and the shells of the internodes 53.67 per cent. The composition of the three portions was as follows:

Analysis of stalks of maize.

Constituents.	Nodes.	Pith of inter-nodes.	Shells of inter-nodes.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Moisture.....	6.52	7.01	4.95
Protein.....	4.38	3.50	2.44
Fat.....	.94	1.17	.78
Carbohydrates other than crude fiber.....	48.21	44.08	43.88
Crude fiber.....	37.94	41.44	46.01
Ash.....	2.11	2.80	1.94

The solubility of the different portions of the stalk in acid and alkali alone and successively was studied, as well as the furfural content of the samples.

"The composition of the samples, as determined by successive digestion with acid and alkali, and determination of the other ingredients on a water-free basis, is shown by the following table:

Composition of pith and internodes of stalks of maize.

Division of stalk.	Proteids.	Fat.	Insoluble carbohy- drates.	Soluble carbohy- drates.	Ash.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Nodes	4.69	1.01	33.81	58.23	2.26
Pith from internodes	3.76	1.26	35.64	56.33	3.01
Shells from internodes	2.57	.82	39.43	44.86	2.04

"These data show that if the matters are treated with both alkali and acid in preparing them for paper pulp they will yield of that material only about one-third of their weight. On the other hand, when treated by an alkali or acid alone they will yield about one-half of their weight as paper pulp."

The kinds and quantities of sugar obtained from the different portions of the stalk by hydrolysis were determined, and also the celluloses as separated by the chlorination process. The results of the study of the stalks was summarized as follows:

"Summing up the results of the investigations, it is seen that the material examined consists of several different kinds of matter. It contains a small quantity of mineral matter, of ash, of proteid matter, and of matter soluble in ether, but is chiefly composed of carbohydrate material. This material is of various kinds. A part of it will yield by hydrolysis with an acid a small quantity of dextrose capable of fermentation. A larger part, on hydrolysis, is converted into a pentose sugar, presumably xylose, incapable of fermentation, but capable of reducing an alkaline copper solution. Another quantity, perhaps larger than that just mentioned, passes into solution under the influence of hydrolyzing agents, but does not seem to produce a sugar capable of reducing alkaline copper solution. The largest portion of carbohydrate matter consists of cellulose of 2 varieties, which may be designated as α and β . Both of these celluloses are insoluble in chlorin, but the β cellulose may be dissolved in dilute nitric acid. The bodies which are capable of yielding furfural consist largely of xylan and allied pentosan substances. There is, however, as the data have shown, a considerable quantity of matter present capable of yielding furfural on distillation with hydrochloric acid, and yet not possessing the properties of pentosan bodies. The character and quantity of this furfural-yielding complex is not known, and requires further investigation for its separation and study. It is evident that the material could not be profitably employed as a source of ethylic alcohol, as the quantity yielded is not quite 2 per cent in weight of the whole mass. The possibility of obtaining methyl alcohol from this matter by distillation in closed retorts is a subject for further investigation."

Corncoobs were found to consist of 1.5 per cent pith and 98.5 per cent shell.

"The pith of the corncob has many of the properties characteristic of that of the stalk; is finer in texture, however, and less absorptive. By experiment it was found that 1 gm. of the air-dry pith absorbs 10.43 gm. of water. The chemical composition of the pith and the shell of the cob are found in the following table."

Chemical composition of corncob.

Constituents.	Pith.	Shell.
	<i>Per cent.</i>	<i>Per cent.</i>
Moisture	8.11	9.08
Protein	2.06	1.75
Ether extract52	.23
Fiber	34.15	32.17
Ash	2.43	1.55

The properties of the cornstalk pith are discussed at some length, and feeding experiments with animals made at the different stations with corn and with maize and with different parts of the stalk are summarized.

Report of the agriculturist, W. P. BROOKS (*Massachusetts Hatch Sta. Rpt. 1897, pp. 9-11, 19-23, 26-37*).—The results of various field experiments, most of which are in continuation of former work (E. S. R., 9, p. 339), are reported.

Fertilizer and soil tests.—Soil tests were made with corn on 2 farms and with potatoes at the station. One of the tests with corn was ruined by wire and cut worms. The results of the other were as follows:

Soil test with corn.

Fertilizer.	Applica- tion per acre.	Increase in yield over unmanured plats.	
		Grain.	Stover.
	<i>Pounds.</i>	<i>Bushels.</i>	<i>Pounds.</i>
Muriate of potash.....	160	36.3	2,203
Nitrate of soda	160	8.3	325
Dissolved boneblack	320	15.3	455
Manure	5 cords.	26.4	3,450
Complete fertilizer:			
Nitrate of potash	160	} 52.5	2,455
Nitrate of soda	160		
Dissolved boneblack.....	320		

In the soil test with potatoes the applications of phosphoric acid, nitrogen, and potash increased the crop on an average 26.6 bu., 11.3 bu., and 7.2 bu. per acre of merchantable tubers, respectively. The application of all 3 elements produced a crop inferior to that where nitrogen and phosphoric acid were applied together. No conclusions are drawn.

The one fourth acre plats used for experiments in manuring corn in previous years (E. S. R., 9, p. 340) were seeded with a mixture of timothy, redtop, and clover without further application of fertilizers. The 2 plats which had received manure alone each season for 6 years yielded on an average 1,403½ lbs. of hay and 78½ lbs. of rowen; while the 2 plats which had received manure and potash for the same period gave a yield of 961¼ lbs. of hay and 536½ lbs. of rowen.

Four ¼-acre plats, 2 of which had been fertilized for 6 years with a special corn fertilizer and 2 with a fertilizer richer in potash than the

special fertilizer but furnishing less nitrogen and phosphoric acid (E. S. R., 9, p. 340), were seeded to timothy, redtop, and clover. The plats which had received the special corn fertilizer gave an average yield of 760 lbs. of hay and 113½ lbs. of rowen. The plats which had received the fertilizer richer in potash yielded on an average 713½ lbs. of hay and 147 lbs. of rowen. It is believed that, owing to inequalities of moisture conditions, the influence of the potash was not clearly shown.

The test with legumes was continued from former years (E. S. R., 9, p. 340). A number of plats had received nitrogenous fertilizers while some received no nitrogen. During some seasons legumes were grown on the plats to test their ability as nitrogen gatherers. The results from a crop of oats grown on the plats last season show "not the least evidence of any ability on the part of the soy bean when grown before a grain crop (and harvested) to make nitrogen manuring of the grain crop unnecessary." Of the nitrogen fertilizers, nitrate of soda gave the largest crop, followed by barnyard manure, dried blood, and sulphate of ammonia, in the order given. Double sulphate of potash and magnesia was more effective than muriate of potash, especially when used in connection with sulphate of ammonia. A test of muriate with sulphate of potash in connection with sulphate of ammonia as a corn fertilizer gave too small a difference in yield to ascertain the merits of the two forms of potash.

Experiments with the rotation of manures on grass lands have been continued (E. S. R., 8, p. 402), and the yields for the last season are reported. "This system of using these different manures for grass lands in rotation has much to recommend it."

Nitragin was tried on crimson clover, alfalfa, and common red clover, but without appreciable effect. "The failure of the material to benefit the crop appears to be due to the fact that our soils contain the nodular bacteria of the common leguminous crops in sufficient numbers."

Sulphate of iron used at the rate of 80 lbs. per acre had a very slight effect, sometimes proving deleterious rather than beneficial.

Variety tests.—The results of variety tests with corn, potatoes, grasses, millets, soy beans, and clovers are reported. The 9 varieties of flint and 11 of dent corn tested all proved to be too late for culture except for silage. Of 81 varieties of potatoes, Rose No. 9, Restaurant, Woodbury White, Bliss Triumph, Prolific Rose, Empire State, Early Maine, Dakota Red, Sir William, Early Rose, and Beauty of Hebron gave the best yields, all yielding at the rate of more than 220 bu. of merchantable tubers per acre.

Sixty species and varieties of grasses were tested, most of them occupying plats containing 1 sq. rod. English rye grass, Italian rye grass, crested dog's tail, and meadow fescue winterkilled. Tall oat grass, tall fescue, red fescue, fowl meadow, Canada blue grass, water spear grass, and wood meadow grass are mentioned as promising grasses.

The results for 21 varieties of millets belonging to the species *Panicum crus-galli*, *P. miliaceum*, and *P. italicum*, grown on plats 1 sq. rod in size, are given in a table. Owing to the small size of the plats, no conclusions as to the relative merits of the different varieties are given. Japanese barnyard millet (*P. crus-galli*), Japanese broom-corn millet (*P. miliaceum*), and Japanese millet (*P. italicum*) yielded at the rate of about 40 bu. of seed per acre. The early white soy bean yielded 18.7 bu. of beans per acre, medium black 16 bu., and medium green 34.7 bu. The test of medium red, mammoth, alsike, and crimson clover was continued from last year (E. S. R., 9, p. 340). Mammoth clover gave the best results. The other kinds were injured to a considerable extent during the winter. The results of a comparison of sulphate and muriate of potash as fertilizers for clover were without special significance. Sweet clover (*Melilotus alba*), grown on the same plat, made a better growth this year than the year before, the yield being at the rate of about 12½ tons per acre. This is believed to be due to a larger supply of the appropriate nodular bacteria in the soil. The crop is recommended for green manuring rather than for fodder.

Experiments with alfalfa, saccaline, crimson clover, winter vetch, Idaho field or coffee pea (*Cicer arietinum*), Brazilian stooling flour corn, and black chaff or African millet are briefly noted. Alfalfa seed treated with Nitragin showed no advantage over untreated seed. Saccaline, crimson clover, Idaho field or coffee pea, and Brazilian stooling flour corn were found unprofitable as fodder crops. Black chaff or African millet resembles Kaffir corn, and both are regarded as inferior to maize for that climate.

Report of the director, H. BENTON (*Alabama Canebrake Sta. Rpt. 1897, pp. 5, 6, 8-11*).—The experiments described comprise culture, variety, and fertilizer tests of cotton; variety and culture tests of corn, and a comparison of standard varieties of potatoes.

Experiments with cotton.—Fertilizer tests were made on a sandy calcareous soil with application of sulphate of ammonia, sulphate of potash, acid phosphate, tankage, cotton-seed meal, and barnyard manure. The results show that acid phosphate applied singly or in combination did not increase the yield. Sulphate of ammonia and sulphate of potash applied alone or in combination gave good results. Sulphate of potash and tankage was found the most profitable combination on these soils. It is concluded from the results of the experiments that the sandy calcareous soils of that region are deficient in potash and ammonia. Shallow preparation of land with the cotton planted on beds gave better results than deep preparation with the cotton planted on the level. Among 7 varieties Truitt gave the best yield of seed cotton.

Experiments with corn.—Land plowed 4 in. deep with the corn planted in beds yielded 24.1 bu. per acre; land plowed 10 in. deep with corn planted on the level yielded 24.2 bu. There was practically no difference in the yields of Huffman Early and Welborn Conscience corn.

Potatoes.—The 4 varieties tested, Peerless, Beauty of Hebron, Early Rose, and Early Vermont, yielded 90, 93.5, 103, and 111 bu. of merchantable tubers per acre, respectively. The total yields ranged from 158.5 to 166.2 bu. per acre. An acre of Bunch Yam sweet potatoes yielded 207 bu.

Tobacco experiments.—A one-half acre plat yielded 335 lbs. of well-cured tobacco. General Grant and Bradley Broad Leaf and Cuban Seed Leaf and Havana Seed Leaf were about equal in yield. The yield of the latter two varieties was about two-thirds that of the former.

Millet, E. C. CHILCOTT and D. A. SAUNDERS (*South Dakota Sta. Bul. 60, pp. 127-140, fig. 6*).—In 1897 a number of varieties of millet were grown in a cooperative experiment with the Division of Agrostology of this Department. The seed was obtained from 13 seed firms in various parts of the United States and was sown on land of uniform quality in drills 2 ft. apart. The soil was cultivated and hoed during the season. Illustrations are given of samples taken at the best stage of growth for cutting for hay. All the varieties received under many different names are classified under the following groups, each of which is briefly described: Common millet (*Setaria italica*), Hungarian millet (*S. italica*), barnyard grass, cocksbur grass (*Panicum crus-galli*), Golden Winter (*S. italica*), broom-corn millet (*P. miliaceum*), and German millet (*S. italica germanica*). Short notes are given on the growth of the varieties.

Forage crops of the James River Valley, J. H. SHEPARD and E. C. CHILCOTT (*South Dakota Sta. Bul. 59, pp. 87-109, pls. 10*).—The experiments described are a continuation of work formerly reported (E. S. R., 9, p. 295) without any material change in the methods of work. About 100 varieties of forage plants, clovers, alfalfa, grasses, millets, peas, rape, spurry, vetches, sorghums, fodder, field and sweet corns, and sunflowers were tested on one-fourth acre plats, and 36 varieties of grasses and clovers were grown on small plats 1 square rod each for the purpose of comparing their habits of growth and their characters. No deleterious effects were produced by artesian well water used in irrigating the plats. The results on all plats are described in brief notes.

Potato experiments, C. VON SEELHORST (*Jour. Landw., 46 (1898), No. 1, pp. 43-49*).—Twenty tubers of the Magnum Bonum variety, similar in form, each having 9 eyes and weighing about 90 gm., were selected and planted in 2 lots. Ten of these tubers were planted and cultivated according to the Güllich method, and the eyes of the other 10 tubers were planted singly 20 cm. apart in rows 50 cm. apart. Of 88 eyes all but 2 grew.

The Güllich method consists in planting whole tubers a meter apart each way, and in bending the stems of the growing plants across each other and covering them well with earth. This extensive hilling is intended to favor the formation of stolons and thus to increase the yield of tubers.

The 10 tubers planted according to the Gülich method yielded 3,800 gm. of large and 500 gm. of small tubers. The 86 eyes of the other 10 tubers yielded 35,700 gm. of large and 2,900 gm. of small tubers. It is stated that in field experiments the results were not so striking, but still considerably in favor of planting the eyes singly. The Gülich method was not conducive to the formation of good-sized tubers. The author believes that hilling interferes with the assimilative functions of the plant.

In another experiment the use of different-sized tubers for seed and planting at different distances were tested on plats equal in size. The plants were grown 20, 40, and 60 cm. apart in rows 50 cm. apart. Large, medium, and small tubers, weighing 90 to 100, 50, and 30 gm. respectively were used for seed. The results are given below:

Yields per plat from different-sized tubers grown at different distances.

Distance between plants in the row.	Large seed tubers.			Medium-sized seed tubers.			Small seed tubers.		
	Large tubers.	Small tubers.	Starch content.	Large tubers.	Small tubers.	Starch content.	Large tubers.	Small tubers.	Starch content.
	<i>Kg.</i>	<i>Kg.</i>	<i>Per cent.</i>	<i>Kg.</i>	<i>Kg.</i>	<i>Per cent.</i>	<i>Kg.</i>	<i>Kg.</i>	<i>Per cent.</i>
20 centimeters.....	151.	8.2	16.6	104	6.5	15.4	81	5	14.7
40 centimeters.....	125.5	4.5	15.8	104	6.5	15.4	78	5	16.2

Sugar beets in Idaho, C. W. McCURDY (*Idaho Sta. Bul. 12, pp. 37-73, figs. 8*).—This bulletin reviews the work with sugar beets in the State, discusses in a popular way the history of the industry, the world's production and consumption of sugar, and the climate, soil, and fertilizers suited to the sugar beet, and considers the factors which enter into the establishment of a beet-sugar factory. A number of varieties of sugar beets are described and compared. The relative worth of the different varieties deduced from analyses made by the station is given in the following table:

Comparison of varieties of sugar beets.

Name.	Maximum sugar content.	Minimum sugar content.	Average sugar content.	Purity.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Degrees.</i>
Kleinwanzleben	19.60	14.40	14.16	82.80
Metta.....	18.40	14.60	13.38	82.78
Vilmorin Imperial.....	18.20	10.60	14.10	85.42
Vilmorin Improved.....	16.60	14.40	11.77	75.55
French Red Top.....	15.90	10.70	13.65	82.70
Lane Imperial.....	15.70	10.60	13.44	81.69
New Danish.....	15.20	10.80	13.83	81.81

Analyses were made of large, medium, and small sized beets of 4 different varieties and the results show the highest sugar content and purity in the medium-sized beets, which weighed about 1 pound. Forty-one samples, including 20 from the station, were analyzed in 1897; the average sugar content was 15.17 per cent, with an average purity of

87.55 per cent. Twenty samples, grown by the station, averaged 15.28 per cent in sugar content and 92.55 in purity, while the rest of the samples gave an average sugar content of 17.07 per cent and the average coefficient of purity was 82.78. The results of analyses made in the chemical laboratory of this Department of samples grown in the State are also tabulated, together with the results obtained at other stations.

Sugar beets, R. H. McDOWELL and N. E. WILSON (*Nevada Sta. Bul. 37, pp. 16, fig. 3*).—This bulletin reviews the work with sugar beets in the State, reports on the work of the season of 1897, and gives directions for the culture of the crop. Vilmorin Improved and Kleinwanzlebener varieties are described and directions for making culture tests are given. The weather conditions for the season and the results of analyses of 22 samples of sugar beets, 10 of which were grown at the station, are tabulated. In shape the beets scored from 78 to 99.7 on a basis of 100, and the sugar content varied from 14.4 to 23.6 per cent. Farmers sent beets to the station varying from 14.4 to 19.4 per cent in sugar content, and reported a yield of 30 tons per acre.

Sugar beets in South Carolina, M. B. HARDIN and J. F. C. DUPRE (*South Carolina Sta. Bul. 31, pp. 1-7*).—This bulletin reports the results of cooperative culture experiments and variety and fertilizer tests with sugar beets.

In 18 samples of beets from different parts of the State the sugar in the juice varied from 7.4 per cent to 15.75 per cent, and the purity ranged from 62.2 to 87.1. No averages are given. Of 9 varieties, Red Top and Henderson White were most productive, each yielding over 12 tons per acre.

Fertilizer experiments were made on 12 plats, 3 of which served as check plats. All plats were fertilized with 160 lbs. cotton-seed meal, 120 lbs. acid phosphate, and 120 lbs. kainit per acre, applied broadcast and harrowed in. In addition to this general application, different amounts of these fertilizing materials and nitrate of soda were applied singly and in various combinations in the drill with the seed. The application in the drill of 100 lbs. nitrate of soda, 200 lbs. acid phosphate, and 400 lbs. kainit per acre gave the largest yield of beets. In general the complete fertilizers were more effective than the applications which furnished but one or two of the elements of plant food.

Experiments with winter wheat, C. A. ZAVITZ (*Ontario Agr. Col. and Expt. Farm Bul. 108, pp. 14*).—This work, which has been in progress for 9 years, comprises tests of varieties from the United States, England, Scotland, Germany, France, Russia, and Canada, and experiments in different dates of seeding, methods of soil preparation, methods of seeding, selection of grain for seed, quantities of seed per acre, application of fertilizers, treatment of smut-infested seed, the yield and quality of wheat cut at different stages of maturity, and the value of seed from wheat cut at different stages of maturity. This bulletin summarizes the experiments of 1898 and gives the average results of

some of the experiments conducted for several years in succession. A previous bulletin on this work has been noted (E. S. R., 7, p. 394).

Ninety-two varieties were sown on plats at the rate of 2 bu. per acre during the first week of September. All varieties ripened between July 14 and 21 and gave an average of 3.4 tons of straw and 42.9 bu. of grain per acre, and an average weight of grain of 63 lbs. per measured bushel. Of 48 varieties grown for 5 years in succession Dawson Golden Chaff, Early Genesee Giant, Egyptian, Imperial Amber, Early Red Clawson, Reliable Golden Drop, Russian Amber, and Egyptian Amber, in the order named, gave the best results, the average yields varying from 45.3 to 52.6 bu. per acre. Among 44 new varieties of winter wheat grown in 1898 Gold Coin, Silver Dollar, White Golden Cross, Pedigree Genesee Giant, Oregon, Forty Fold, and Zerena were the most productive, yielding from 50 to 52 bu. per acre. The average yield of Dawson Golden Chaff and Early Genesee Giant, grown for 3 years in succession on 25-acre fields, was about 36 bu. per acre. The average results for 5 years show that Egyptian Amber, Emporium, Bissell, Long Berry Red, Turkish Red, and Geneva were least affected with rust. During a period of 9 years there has been a variation from 26.1 to 52.9 bu. in the average yield of grain per acre, from 1.2 to 4 tons in the average yield of straw per acre, and from 55 to 63.3 lbs. in the average weight of grain per measured bushel.

The results from the test in seed selection show that large plump seed produced 6.3 bu. per acre more than small plump seed and 8.25 bu. more than shrunken seed. Seed grain which had been broken in threshing yielded only one-fifth as much as large plump seed.

The results of sowing winter wheat on different dates indicate that best results are obtained by sowing during the last week in August or the first week in September.

In tests conducted for 5 years in succession $1\frac{1}{2}$ bu. of seed per acre gave better results than 1 bu. per acre and similar results to using 2 bu. of seed per acre. It was also found that sowing broadcast and drilling with the grain drill gave results practically alike. The following table gives the results of experiments in the preparation of soil for winter wheat:

Results of preparing land in different ways for winter wheat.

Soil preparation, 1896 and 1897.	Average results for two years (4 tests).				
	Height of crop.	Crop lodged.	Weight of grain per measured bushel.	Yield per acre.	
				Straw.	Grain.
	Inches.	Per cent.	Pounds.	Tons.	Bushels.
20 tons farmyard manure per acre on bare summer fallow	52.4	45.0	60.8	3.4	40.4
Peas plowed under	51.7	31.3	60.8	2.7	37.0
Bare summer fallow	52.3	40.0	60.7	2.6	35.0
Rape plowed under	50.7	30.8	60.4	2.4	33.7
Crimson clover plowed under	50.7	22.5	60.5	2.3	31.2
Buckwheat plowed under	50.5	17.5	60.4	2.0	29.9

A study of the effect of cutting grain at different stages of maturity for several years in succession showed that the largest yield of grain and the best quality of seed were produced from the crop which was allowed to mature before cutting.

Experiments in treating seed wheat for the prevention of smut were conducted for 3 years. Grain from untreated seed contained an average of 170 smut balls per pound, while seed treated with potassium sulphid produced an average of 12 smut balls and that treated with either copper sulphate or hot water less than 1 ball of smut per pound of grain.

Some of the results of cooperative experiments with winter wheat published elsewhere (*E. S. R.*, 10, p. 36) are given in the bulletin.

Wheat, winter oats, barley, and lime experiments, R. H. MILLER and E. H. BRINKLEY (*Maryland Sta. Bul.* 56, pp. 153-166).—The experiments consisted of variety tests of wheat and winter oats; a study of the effects of lime on the production of wheat, hay, and corn; a test of lime and cowpeas as a preparation for wheat; trials of seeding winter oats at different times; and a test of the hot-water treatment of barley seed for the prevention of smut.

The results of variety tests of wheat made in 1896 and 1897 are tabulated. Among the varieties tested for 6 years Fultz gave the highest yield, 37.8 bu. per acre, followed by Currell Prolific, Wisconsin Triumph, and Valley, yielding 36.2, 34.9, and 33.7 bu. per acre, respectively. Beal, Ruby, Terry, and Rocky Mountain are considered promising new varieties.

Different amounts of lime up to 40 bu. per acre, applied to a number of wheat plats, showed that the increase in yield was in direct proportion to the amount of lime applied, but larger applications did not give satisfactory results. To test the effect of lime and cowpeas as a preparation for wheat, 2 plats of very poor soil were prepared for seeding in the spring. One plat received an application of 40 bu. of stone lime and then cowpeas were drilled in on both plats at the rate of 5 pk. per acre. The growth of the cowpeas was best on the limed plat. The cowpeas were plowed under and the plats were sown to wheat and timothy in the fall and clover was sown on both plats the next spring. There was an increase of only 1.6 bu. per acre in the yield of wheat on the limed plat, but this plat has "a very fine stand of both clover and timothy, while there is scarcely any clover and a poor stand of timothy on the plat receiving no lime." The test of the effect of lime on hay and corn showed a decided gain for both crops in favor of the limed plat.

The varieties of winter oats tested were Hatchett, Black Winter, Winter, and Virginia Gray, the latter producing the best yield. For 2 years in succession better results were obtained from sowing winter oats September 1 than from sowing September 15 and 30.

Hot-water treatment of seed barley proved effective in the prevention of smut. The plat on which the seed had been treated had practically

no smut, while on the plat which had been seeded with untreated seed from 15 to 20 per cent of the heads were smutted.

Field experiments with wheat, oats, and barley, L. A. MERRILL (*Utah Sta. Bul. 56, pp. 171-193*).—Variety tests of wheat have been carried on for a number of years and the report of this work is here given in detail. Of 16 varieties of spring wheat and 14 varieties of winter wheat, the following have given an average yield of over 20 bu. per acre:

Results of variety tests of wheat.

Kind.	Years.	1891.	1892.	1893.	1894.	1895.	1896.	1897.	Average.
Spring wheat:		<i>Bu.</i>	<i>Bu.</i>	<i>Bu.</i>	<i>Bu.</i>	<i>Bu.</i>	<i>Bu.</i>	<i>Bu.</i>	<i>Bu.</i>
Common.....	2	16.89	34.42	25.65
Gillings's mixture.....	2	22.00	29.12	25.56
Niagara.....	6	19.00	16.66	13.21	26.44	16.89	33.76	20.99
Whittington.....	5	15.55	14.44	17.11	24.22	32.43	20.75

Fall wheat:									
Sonora.....	2	33.39	15.33	24.36
Early Red Clawson.....	2	17.65	22.99	20.32
Red Cross.....	2	23.61	16.55	20.08

In 1897 34 varieties of fall wheat were tested on small plats. The seed was obtained from the Ontario Agricultural and Experimental Union and the Kansas Experiment Station. Early Ripe, Velvet Chaff, Siberian, and Turkey, in the order given, produced the best yields. "In irrigated districts fall wheat will not do as well as spring wheat under the same treatment."

A test of sowing different quantities of wheat per acre has been previously reported (E. S. R., 6, p. 543). It was shown by an experiment that irrigating fall wheat in the fall, when there is sufficient rain to bring up all the grain, is detrimental to the yield of grain and straw. The best results were obtained by one irrigation made in the spring. In this experiment fall wheat produced slightly better results than spring wheat under the same treatment.

Results of experiments indicated that sowing wheat in November is better than sowing wheat earlier and that drilling is better than broadcasting for fall sowing. A plat rolled after seeding gave slightly better results than a plat rolled before seeding or a plat left unrolled.

The results of variety tests of oats for a number of years are given in tables and a number of the leading varieties described. The varieties recommended are American Banner, Canada White, Badger Queen, Wide Awake, Clydesdale, Nameless Beauty, American Beauty, and Prince Edward Island. The last-named variety is a prolific black oats. The results of experiments indicate that oats should be sown at the rate of 2 bu. per acre. For 4 years oats sown April 12 gave better results than oats sown May 10 or June 1.

Of 4 varieties of barley grown at the station for 6 years or more, Lump Blue gave the best results, the average yield being 32.43 bu. per acre. A number of varieties are described and the results of all varieties are given in tables.

The influence of a temporary low temperature on the development of winter grains when sown in spring, C. VON SEELHORST (*Jour. Landw.*, 46 (1898), No. 1, pp. 50, 51).—Four pots each of winter rye, winter wheat, and winter rape, 2 weeks after the seed had been sown, were kept at a temperature of from 0 to 2° C. for 2 weeks; and 6 of these pots were then placed in the open air and restored to natural conditions of growth. The other 6 pots were kept at this temperature for 1 week longer and then placed in a temperature of 5 to 7° C. below freezing for another week. Each pot produced ripe grain. The series of pots which had been subjected to a low temperature for the shorter period of time ripened about 2 weeks before the other series. The rape ripened during the latter part of July, the rye during the latter part of August, and the wheat during the first half of September. The author concludes that a temporary low temperature during the early vegetative period as tested in these experiments hastens the development of the plant. It is found in practice that winter grains when sown in spring either do not head during the following summer, or that the heading is very incomplete.

On the influence of smaller and larger amounts of water on the development of some cultivated plants, A. MAYER (*Jour. Landw.*, 46 (1898), No. 2, pp. 167-181).—Pot experiments during a number of years with rye, wheat, barley, and oats are reported, in which the moisture content of the soils was maintained uniformly at fixed percentages of their total water capacity from very wet to very dry (10 to 96 per cent). As a rule the less the moisture the greater the relative yield of grain, and as a consequence the less the percentage of fiber the greater the percentage of protein and pure albuminoids and the shorter the period of growth. The presence of large amounts of water in the soil apparently tended to check seed production and caused the formation of fiber instead of carbohydrates. As regards water requirements, the plants experimented with stood in the following order: Oats, wheat, rye, and barley. In one series of experiments the optimum percentages of water for the different crops seemed to be as follows: For oats 90 per cent of the water capacity of the soil, wheat 80 per cent, rye 75 per cent, and barley 62 per cent. The results of other experiments, however, show that these figures can not be accepted as definitely fixing the relative water requirements of these crops.

Notes on flax and hemp, H. T. FRENCH (*Oregon Sta. Bul.* 54, pp. 1-11, pl. 1, figs. 2).—The results of culture experiments on flax and hemp are briefly discussed and notes on the method of growing these crops are given. Four varieties of flax—Belgian, Pure Riga, Finest Dutch Sowing, and White Balsam Dutch—were grown in comparison and their relative merits, so far as determined from one year's experiments, are pointed out.

Variety tests of potatoes, A. SEMPOLOWSKI (*Deut. Landw. Presse.* 25 (1898), No. 39, p. 1024).—Thirty-three varieties were tested and the results are here reported in tables and discussed. The variety Wohltmann gave the best results.

Second report on potato culture, I. P. ROBERTS and L. A. CLINTON (*New York Cornell Sta. Rpt.* 1898, pp. 385-406, figs. 4).—A reprint of Bulletin 140 of the station (E. S. R., 9, pp. 1044, 1060, 1072).

Cultivation of ramie in foreign countries (*Spec. [U. S.] Consular Rpts., 15 (1898), pp. 111-150*).—Reports are given by the United States consuls on the cultivation of ramie at Amoy, Chefoo, Chungking, Fuchan, and Hankau, China; Calcutta, India; Yokohama, Japan; Seoul, Korea; Jamaica, and Guatemala.

Sugar beets, W. A. WITHERS (*North Carolina Sta. Spec. Bul. 49, folio*).—Directions for growing sugar beets, given with a view to conducting cooperative culture experiments.

Sugar-beet investigations, J. L. STONE, L. A. CLINTON, G. C. CALDWELL, ET AL. (*New York Cornell Sta. Rpt. 1898, pp. 497-574, figs. 9*).—A reprint of Bulletin 143 of the station (E. S. R., 10, p. 143).

Notes on field experiments with tobacco in Massachusetts, 1893-1896, C. A. GOESSMANN (*Massachusetts Hatch Sta. Rpt. 1897, pp. 128-136*).—The experiments are briefly described and the results tabulated. These experiments were reported in a former bulletin of the station (E. S. R., 9, p. 345).

Winter oats, SCHACHT (*Deut. Landw. Presse, 25 (1898), No. 73, p. 789*).—Practical notes on growing winter oats with reference to seed and fertilizers.

Variations in the water content of shelled corn (*Deut. Landw. Presse, 25 (1898), No. 98, p. 1017*).—The quality of the grain, the weather, and the methods of storing are given as the factors which influence the water content. The variations in the water content for each month are given. It is stated that considering the normal water content of Hungarian varieties of corn to be 12 per cent, their starch content varies from 57 to 65 per cent.

Experiments with alinit, O. LEHMANN (*Deut. Landw. Presse, 25 (1898), No. 85, pp. 905, 906*).—Oats and barley were inoculated with alinit before sowing and the effect of alinit as a fertilizer compared with that of nitrate of soda. The oats plats received a general application of kainit and Thomas slag, and the barley plats received combinations of Thomas slag, quicklime, and kainit, in addition to alinit or nitrate of soda. The results show that alinit failed to increase the yield of either crop perceptibly, while nitrate of soda in both cases gave an increase in yield in proportion to the amount applied.

Two tests of alinit, J. LUTOSLAWSKI (*Deut. Landw. Presse, 25 (1898), No. 87, p. 920*).—Seed wheat was inoculated with alinit and the resulting crop compared with wheat grown from uninoculated seed. The tests were made by two different parties. In one case the inoculated seed gave a smaller and in the other a larger yield than the uninoculated seed.

Concerning alinit, SALFELD (*Deut. Landw. Presse, 25 (1898), No. 91, p. 963*).—A note stating that quicklime applied as a fertilizer is not detrimental to the action of alinit or inoculating soils.

Alinit, V. ALPE (*Prog. Agr. et Vit., 30 (1898), No. 51, pp. 739-741*).—The author quotes the investigations of a number of experimenters with this substance and concludes it is probably without practical value. Comparing it with nitrate of soda as a fertilizer the yield of rye was 3 times as great where soda was used as where alinit was employed. Dr. Gerlach is quoted as having found it, instead of a pure culture as is claimed, a mixture of at least 5 distinct species of bacteria.

HORTICULTURE.

Fertilizers for garden crops, W. P. BROOKS (*Massachusetts Hatch Sta. Rpt. 1897, pp. 23-26*).—This is a report of an experiment with peas, beets, squashes, and celery to compare sulphate of ammonia, nitrate of soda, and dried blood as sources of nitrogen, and sulphate of potash with muriate of potash as sources of potash. Phosphoric acid was furnished in all cases in the form of dissolved boneblack. The fertilizers in each case supplied phosphoric acid at the rate of 50.4 lbs., nitro-

gen 60 lbs., and potash 120 lbs. per acre. Tables are given showing the yields of the different crops of the various plats. In the case of beets and peas sulphate of potash appeared distinctly superior to muriate of potash. With peas, dried blood gave a somewhat larger crop than nitrogen in other forms and with beets nitrate of soda was greatly superior to the other forms. When sulphate of ammonia and muriate of potash were used together, the growth of both peas and beets was decidedly inferior to that where other combinations were used. The injurious effect is ascribed to the formation of ammonium chlorid. The celery and squashes were failures on account of unfavorable weather.

The reciprocal effect of stock and scion, L. DANIEL (*Jour. Soc. Nat. Hort. France, Congrès Horticole, 1898, pp. 95-112*).—The subject is treated under two heads—the direct reciprocal influence of the scion and stock, and the indirect influence of the stock upon the offspring of the scion. Many of the results given have previously been reported (*E. S. R.*, 5, p. 1089; 9, p. 945). Precautions were taken to prevent hybridization. The following conclusions are given:

The reciprocal effect of stock and scion can not be denied, though it does not always act with the same intensity. This effect is divided into effects of general nutrition, shown in size, vigor resistance to parasites, etc., and effects of a specific nature seen in both external and internal morphological characteristics of vegetative organs, as in *Helianthus*, and of reproductive organs, as in beans and *Solanaceæ*. The effects of a specific nature are more pronounced in cases of mixed grafting, while the general effects are decreased by mixed grafting and increased by ordinary grafting. The variations due to grafting are often hereditary, appearing in the first seed generation.

There are numerous practical applications of the reciprocal effect of scion and stock, such as increase in the size of fruits, improvement of the flavor of fruits and certain vegetables, production of new varieties in which the color of the flower, the form of the fruit, or the vegetative organs are modified. The effects of grafting are more marked in herbaceous than in woody plants, and also more marked in the offspring of the grafted plant than in the plant itself. Grafting, as a means of retaining variations acquired under culture, is useful only in the case of trees, and the difference between seedling fruit trees and the varieties producing them may be explained in part by the effect of grafting on the progeny of grafted plants.

Grafting which produces a variation in the seed may be used to produce new varieties. Since this variation can frequently be directed in a given way, it is possible almost to a certainty by repeated graftings to impart definite characteristics of flavor, form, color, etc., to plants which vary readily under culture. In the case of other plants grafting may produce variations which, though difficult to obtain, after once appearing, may be directed in a definite way.

Methods of tree planting, F. W. CARD (*Nebraska Sta. Bul. 56, pp. 11-24, figs. 1*).—In this bulletin the author describes various experiments

in tree planting and makes suggestions for planting apple trees under the conditions prevalent in eastern Nebraska. At the end of the second year of an experiment to determine how old trees should be when planted, the average size of the different sets decreased in the following order: Three-year-old trees, two-year whips and two-year tops on three-year roots, two-year limbed trees, and one-year trees; but not in all cases in proportion to the differences in their ages when planted. While in the opinion of the author it is much too soon to pass final judgment upon these results, he remarks that "two-year limbed trees are eminently satisfactory and desirable for ordinary planting, but with good care even one year-old trees may give good results and gain on older trees planted at the same time." On the method of digging large holes through the compact subsoil and filling these with mellow surface soil in which to plant the trees, no conclusions could as yet be drawn from the experiments. Several methods of root pruning were tried, which varied from cutting the roots back to only 1 or 2 in. in length to leaving them wholly untrimmed, just as received from the nursery. The author says: "These experiments indicate that all healthy roots which are found on a tree as shipped from the nursery should be left there in planting. The results upon this point are more emphatic than upon any other question embraced in the experiments." There appeared to be no advantage in making a fresh, clean cut at the ends of sound roots. The conclusions drawn from the experiments on top pruning are unfavorable to cutting back apple trees severely at planting time. Those left entirely unpruned or with the branches shortened about one-half did better than those pruned to a cane or grown as a whip in the nursery.

Cooperative experiments on fall planting were conducted at the Nebraska Station and by H. C. Irish at the Missouri Botanical Garden, at St. Louis, Missouri, the object being to determine if root growth can take place while the tops are dormant. The experiments at both places showed that fall-planted trees do make some root growth in the autumn succeeding planting, and in the spring before the leaves start. While the experiments were not designed to determine the desirability of fall planting, the author says they indicate that in the locality of St. Louis fall planting gives good results, but upon the plains it is generally found to be unsatisfactory, owing largely to the dry open winters.

Ornamental planting, F. W. CARD (*Nebraska Sta. Bul. 55, pp. 10, figs. 7*).—This bulletin treats of the lawn, and the arrangement, grouping, and choice of plants in ornamenting the home. A list of some ornamental plants suitable for Nebraska planting, with descriptive notes, is given. Among those found satisfactory at the station are the following: *Shrubs*.—*Spiræa*, sand cherry, *Rosa rugosa*, button bush, red branched dogwood, tamarix, viburnums, syringas, honeysuckles, sumachs, snowberry, juneberry, and gooseberry. *Climbers*.—Virginia creeper, wistaria, wild clematis, hop, and wild grape. *Herbaceous perennials*.—*Gaillardia grandiflora*, golden marguerite, perennial sweet pea.

Notes on cold storage, F. W. RANE (*Amer. Gard.*, 19 (1898), No. 191, pp. 634, 635).—This is taken from a paper read before the Society for the Promotion of Agricultural Science. The author gives an account of a method of cold storage which has been tried at the New Hampshire Station and describes the construction of a storage room built in the cellar of the station barn.

“There are few days at a stretch from September until late in spring in New England, for instance, but that the temperature falls at some time sufficiently to utilize it for cold storage. Being prepared to retain this temperature in cellars or buildings constructed for the purpose until a similar or lower temperature is again realized is the key to its success. From experience it is believed this simple method can with comparatively little care and expense be made more useful at present (in this our transitory stage) than all others. The ordinary house cellar or portion of a barn cellar will answer for the storage room if the simple principles of construction for the retention of dry cold air as well as a proper system of ventilation are considered.”

The following temperatures are said to be the most satisfactory for the preservation of some common fruits and vegetables: Apples, 30 to 45°; berries, 36 to 40°; celery, 35°; cranberries, 34 to 38°; peaches, 45 to 55°; pears, 36°; onions, 34 to 40°; potatoes, 36 to 40°; asparagus, 34°; cabbage, 34°, and grapes, 36 to 38°.

Report of the horticulturist, S. T. MAYNARD (*Massachusetts Hatch Sta. Rpt.* 1897, pp. 71-73).—An outline of the work of the year.

Garden crops in the James River Valley, J. H. SHEPARD and E. C. CHILCOTT (*South Dakota Sta. Bul.* 59, pp. 109-124, figs. 6).—Notes on variety tests of onions, spinach, salsify, leeks, chicory, kohlrabi, parsnips, radishes, lettuce, carrots, beets, mangels, turnips, ruta-bagas, and beans, with a list of the following varieties recommended as well adapted to the State: *Tomatoes*.—Salzer First of All, and Early Ruby. *Cabbage*.—Salzer Earliest, Jersey Wakefield, Henderson Succession, Ideal, and Flat Dutch. *Celery*.—Self-Blanching, Giant Pascal. *Squashes*.—Summer Crookneck, Stickler Summer Crookneck, Hubbard, Sibley, and Giant Chili. *Cucumbers*.—Fardhook and Boston Pickling. *Watermelons*.—Early varieties. *Muskmelons*.—Rough-skinned, strongly netted varieties.

Vegetable culture, J. M. FITCH (*Lawrence, Kans.: F. Barteldes & Co.*, pp. 30).—Brief, practical suggestions for the culture and selection of the most profitable vegetables for market or home use.

Nitrate of soda in garden culture: Its adulterations, H. DAUTHENAY (*Rev. Hort.*, 70 (1898), No. 23, pp. 561, 562).—Notes the advantageous use of nitrate of soda on “all vegetables that should remain in the soil a minimum of time and at the same time give a maximum return.” Directions are given for detecting adulteration, which often occurs.

Studies and illustrations of mushrooms, G. F. ATKINSON (*New York Cornell Sta. Rpt.* 1898, pp. 337-366, figs 26).—A reprint of Bulletin 138 of the station (E. S. R., 9, p. 646).

The apple in North Carolina, W. F. MASSEY (*North Carolina Sta. Bul.* 149, pp. 307-325).—A popular bulletin giving suggestions as to the culture of apples in North Carolina.

History of the York Imperial apple (*Montana Fruit Grower*, 8 (1898), No. 28, p. 1).

History of the Yellow Newton apple (*Montana Fruit Grower*, 8 (1898), No. 30, p. 4).

The Fameuse apple as the head of a family, J. CRAIG (*Amer. Gard.*, 20 (1899), No. 212, p. 27, fig. 1).—Notes on the introduction of this variety into America, some of its seedlings, and a description of the Scarlet Pippin.

The plum and its culture, J. W. KERR (*Amer. Gard.*, 19 (1898), No. 210, pp. 889, 890).—This is a paper read before the Maryland Horticultural Society. The author makes a plea for "American plums for America," and discusses the relative merits of American and Japanese plums in this country.

The early botanical views of *Prunus domestica*, F. A. WAUGH (*Bot. Gaz.*, 26 (1898), No. 6, pp. 417-427).—The author gives the synonymy of the early varieties of this species, with notes and discussions.

The botany of plums and cherries, C. E. BESSEY (*Rpt. Nebraska Hort. Soc.*, 26 (1895), pp. 163-178, figs. 12).—Systematic descriptions are given of the various species of the genus *Prunus*, from which have been developed the cherries, plums, almonds, and apricots of cultivation.

Third report upon Japanese plums, L. H. BAILEY (*New York Cornell Sta. Rpt.* 1898, pp. 369-382, figs. 9).—A reprint of Bulletin 139 of the station (E. S. R., 9, p. 1053).

On the dropping of the buds of peach trees, C. MAYER (*Agr. Jour. Cape of Good Hope*, 13 (1898), No. 11, pp. 698-701).—Observations, discussion, and a list of varieties badly affected, less affected, and hardly affected.

The botany of the bush fruits, F. W. CARD (*Rpt. Nebraska Hort. Soc.*, 27 (1896), pp. 241-256).—The botany of the more important bush fruits is given, in which are described the species of raspberry, blackberry, currant, gooseberry, Juneberry, Buffalo berry, tree cranberry, and goumi (*Elaeagnus*). The author describes 18 species of *Rubus* and 8 of *Ribes* in cultivation.

Notes on the botany of the strawberry, C. E. BESSEY (*Rpt. Nebraska Hort. Soc.*, 27 (1896), pp. 227-240).—Descriptive notes are given of the 11 species of *Fragaria* which are cultivated to a greater or less degree. It is stated that 7 are native to North America, the others being native to Europe, Asia, and South America.

Mixed grapes: Singular results from crossing different varieties, C. P. CLOSE (*Amer. Gard.*, 19 (1898), No. 208, p. 857).—Notes on crosses made with varieties of grapes of all colors. In every instance but one the resulting cluster was the same color as the female parent.

The botany of the grape, C. E. BESSEY (*Rpt. Nebraska Hort. Soc.*, 26 (1895), pp. 7-26, figs. 12, maps 2).—The author gives botanical descriptions of 11 species of grapes which are cultivated to a greater or less extent, together with notes on their geographical distribution, their nativity, and the more important varieties which have been developed from each.

The effect of the graft on the flavor of the fruit (*Gard. Chron.*, 3. ser., 24 (1898), No. 614, p. 246; *Agr. Jour. Cape of Good Hope*, 15 (1898), No. 11, pp. 703-705).—Abstracts and discusses the results of experiments made by M. Daniel relating to the reciprocal influence of the scion on the stock, and *vice versa* (see p. 637).

The modern practical cut-flower grower, O. SCHMERBUSCH (*Der praktische Schnittblumenzüchter. Bonn*, pp. 224).—An eminently practical work, based on the author's own experience. An important feature is the tabulation of both cost of production and profits under each method of culture.

The principles and practice of bulb growing, W. C. WORSDELL (*Gard. Chron.*, 3. ser., 24 (1898), No. 625, pp. 442, 443, figs. 5).—One of a series of articles on this subject.

The white cattleyas, H. T. CLINKBERRY (*Amer. Gard.*, 19 (1898), No. 209, pp. 880, 881).—A list of the white varieties, with descriptive notes.

Caladiums, anthuriums, alocasias, and other hot-house aroidæ, J. RUDOLPH (*Caladium, anthurium, alocasia, et autres aroïdées de serre. Paris*, pp. 223, figs. 28).—A strictly horticultural and practical work.

The cultivated species of *Bulbophyllum* (*Wiener Illus. Gart. Ztg.*, 22 (1898), No. 11, pp. 388-392).—A list of the species, with descriptive and cultural notes.

Fourth report upon chrysanthemums, W. MILLER (*New York Cornell Sta. Rpt.* 1898, pp. 657-689, figs. 12).—A reprint of Bulletin 147 of the station (E. S. R., 10, p. 438).

The year's work in chrysanthemums, E. D. SMITH (*Amer. Gard.*, 19 (1898), No. 210, p. 897).—A tabulated report of the work of the committees of the Chrysanthemum Society of America.

Chrysanthemums—certificated varieties of 1898, J. E. WHYTE (*Florists' Exchange*, 10 (1898), No. 50, pp. 1177-1179, figs. 25).—Photographs and originators' descriptions of 25 out of 32 varieties certificated by the Chrysanthemum Society of America during 1898.

Specimen bush-grown chrysanthemums—how a successful exhibitor does the work, W. C. RUSSELL (*Amer. Gard.*, 19 (1898), No. 207, pp. 837, 838, pls. 3).

The bladder ferns (*Cystopteris*) (*Garden*, 54 (1898), No. 1413, p. 485, fig. 1).—Botanical and cultural notes. Especially describes a new method of growing *Chrysopteris montana*. For many years the culture of this species has been considered very difficult. The culture suggested, which is stated to be "as simple as effective," consists in excavating a pit and filling it to the depth of 12 in. with coarse and small brick rubble and covering with only a very little loam and leaf mold, in which the rhizomes are planted.

Bulbous irises (*Garden*, 54 (1898), No. 1412, pp. 470, 471, pl. 1, figs. 4).—Cultural notes and a list of the varieties best adapted for cultivation.

Raising palms from seed, C. W. RANKIN, M. HORVATH, M. MUNTE, and J. E. HINKLE (*Amer. Gard.*, 20 (1899), No. 211, pp. 3-5).—Essays submitted in competition for a prize.

Placeas (*Garden*, 54 (1898), No. 1414, pp. 510, 511, pl. 1).—Botanical and horticultural notes.

About pruning roses, J. MEEHAN (*New England Florist*, 4 (1898), No. 42, p. 509).

The hardy sumachs, W. J. BEAN (*Garden*, 54 (1898), No. 1414, pp. 505-507, pls. 4).—Descriptive and cultural notes and list of hardy species.

The beginning of the culture of plants under glass, G. GIBAULT (*Jour. Soc. Nat. Hort. France*, 3. ser., 20 (1898), pp. 1109-1117).—Notes upon the industry in ancient Rome and its renaissance in France.

Notes on watering, F. CRANFIELD (*Amer. Florist*, 14 (1899), No. 554, pp. 698, 699).—Report upon experiments pointing to the conclusion that the growth of ordinary greenhouse and garden crops is not affected by the temperature of any water usually available for irrigation purposes.

Greenhouse heating, H. W. GIBBONS (*Amer. Gard.*, 19 (1898), No. 204, pp. 789-791).—The author discusses the relative merits of steam and hot-water heating for particular purposes and considers the arrangement of pipes, boilers, etc.

FORESTRY.

Internal temperatures of tree trunks, R. A. EMERSON (*Proc. Nebraska Acad. Sci.*, 6, 1896, pp. 245-252, figs. 4).—Observations on the internal temperatures of tree trunks and limbs were made continuously during the summer of 1894, and at intervals during the spring and summer of 1896, and the winter of 1896-97. Temperatures were taken in several apple trees, a cottonwood, a box-elder, and a maple. During the first summer temperatures were taken regularly from one to three times daily. After that readings were made hourly and in some cases at intervals of 5 to 10 minutes throughout a considerable part of the day. Temperatures were taken at the center and at the surface of trunks and limbs when exposed to direct sunlight and when shaded by foliage and by screens, and these were compared with temperatures taken in the air, both in shade and in sunlight. The temperatures of live limbs were compared with those of sound dead limbs as found and after being soaked in water. A brief account is given of the methods used in taking the temperatures. Charts are given showing

the changes in temperature of the air and of limbs under various conditions.

When the trunks and limbs of trees are shaded their temperatures, if above the freezing point of water, vary according to the temperature of the outside air, but show somewhat smaller diurnal variations and change more slowly, so that in shade tree temperatures above 0° C. are higher than the air temperature when both temperatures are falling and lower when both are rising. On the other hand, when exposed to strong sunlight, again provided their temperatures are above the freezing point of water, limbs and trunks of trees exhibit much greater diurnal variations of temperature, much greater maximum daily temperatures, and quicker changes in temperature than shaded limbs, and even than the outside air, so that in strong sunlight tree temperatures above 0° C. are higher than the air temperature, not only when both temperatures are falling, but are often higher also when both are rising. One side of even a small limb may therefore have a temperature much higher than the air and the opposite side at the same time a temperature lower than the air. The temperatures of the center of limbs change more slowly than those of the surfaces and the extreme daily variations of temperature are less. Above the freezing point of water, the temperatures of water-soaked dead limbs behave like those of live limbs, while the temperatures of normal dead limbs change more quickly than those of live limbs and the extreme daily variations of temperature are greater. The temperatures of normal dead limbs, like the temperature of the air, in both rising and falling, pass the freezing point of water without appreciable retardation. The temperatures of water-soaked dead limbs, in both rising and falling, are noticeably retarded at or near the freezing point of water, but having once passed this point proceed rapidly again. The temperatures of live limbs, in rising, behave like those of water-soaked dead limbs; in falling, however, they are not only retarded at the freezing point of water, but even after having passed this point their descent continues slow.

An observation on annual rings, F. W. CARD (*Proc. Nebraska Acad. Sci.*, 6, 1896, pp. 243, 244).—The author conducted an experiment to ascertain the relation between growth rings and annual rings in trees. A piece of bark was removed early in the season from the north side of an ash tree and also from a maple. Later in the season both trees were stripped of the leaves, which were renewed within 3 weeks. In November both trees were cut down and a cross section made where the bark had been removed, and the ring of growth for that year was apparently as uniform as for others. It seems probable that a greater interference with normal conditions of growth than that in the experiment is necessary to produce more than one growth ring in a season.

Osier culture, J. M. SIMPSON (*U. S. Dept. Agr., Division of Forestry Bul.* 19, pp. 27).—The author gives a historical sketch of the cultivation and use of osiers, together with notes on their geographic distribution and characteristics. The subject of varieties is treated at

some length. Among the European willows which are said to be most suitable for basket making are the following: *Salix amygdalina*, *S. lucida*, *S. fragilis*, *S. caprea*, *S. prunifolia*, *S. viminalis*, and *S. purpurea*. Notes are given on the selection and preparation of soil, with directions for preparing cuttings, planting, cultivation, fertilizing, and harvesting the product. The more common and troublesome fungus diseases and insect enemies are noted, together with suggestions for the prevention of their attacks. Notes are given on the manufacture of willow ware, cost of basket making, production and price of osiers in this country, and quotations are given from letters stating experiences of various American growers. For the benefit of persons interested in osier culture a list of the principal willow growers of this country is appended.

Experimental tree planting in the plains, C. A. KEFFER (*U. S. Dept. Agr., Division of Forestry Bul. 18, pp. 91, pls. 5, fig. 1*).—The effect of heat, light, moisture, soil and soil moisture, and atmospheric moisture as affecting tree growth is stated and notes given on the introduction of exotic trees, hardiness, rules for mixing species, pure planting, mixed planting, nurse trees, and the use of evergreens in Western planting. The objects of experimental plantations are stated, and a list of 39 species of trees employed in these plantings of trees, as follows: Conifers: *Pinus strobus*, *P. resinosa*, *P. ponderosa scopulorum*, *P. divaricata*, *P. sylvestris*, *P. austriaca*, *Larix laricina*, *L. europaea*, *Picea canadensis*, *P. excelsa*, *Pseudotsuga taxifolia*, *Abies concolor*, and *Juniperus virginiana*. Broad-leaved species: *Juglans nigra*, *Populus tremuloides*, *P. deltoides*, *P. certinensis*, *Betula alba*, *B. lutea*, *B. lenta*, *Ostrya virginiana*, *Castanea dentata*, *Quercus alba*, *Q. macrocarpa*, *Q. prinus*, *Q. platanoides*, *Q. rubra*, *Ulmus americana*, *Morus alba tatarica*, *Liriodendron tulipifera*, *Prunus serotina*, *Gleditsia triacanthos*, *Robinia pseudacacia*, *Acer saccharinum*, *A. negundo*, *Fraxinus americana*, *F. lanceolata*, *Catalpa speciosa*, and *Artemisia abrotanum tobolskianum*.

The experimental plantations of Kansas, Nebraska, Colorado, South Dakota, Utah, and Minnesota are described and the results as far as shown by the experiments are stated. Notes are given on growing evergreens from seed and directions for the preparation of an evergreen seed bed are included.

List of publications relating to forestry in the Department Library (*U. S. Dept. Agr., Library Bul. 24, pp. 93*).—This bulletin contains a list of the works relating to forestry in the library of this Department, together with the forest library of the late Prof. Franz von Baur, which was purchased by this Department in 1897. A catalogue is arranged by authors with a separate list of serial publications and a subject index. No works have been included which do not have a direct bearing on the subject, and those relating to landscape gardening and botany are purposely omitted.

Check list of the forest trees of the United States, G. B. SUDWORTH (*U. S. Dept. Agr., Division of Forestry Bul. 17, pp. 144*).—This publication is a revised and condensed edition of Bulletin 14 of the division (E. S. R., 9, p. 452), and contains the scientific and common names of the trees of North America, the synonymy and explanation of the former bulletin being omitted. In order to secure better identi-

fication and to increase the value of the list a geographical range of species has been added in a concise form. The present list comprises an enumeration of the trees indigenous to the United States, 195 in number, and a few thoroughly naturalized and natural and artificial varieties and hybrids have been also cited.

The red beech in coppice and forest tree growth, H. FISCHBACH (*Allg. Forst u. Jagdw. Ztg.*, 74 (1898), No. 12, pp. 377-379).

On the histology of the pine, E. STRUMPF (Anzeig. Akad. Wiss. Krakau, 1898, No. 7, pp. 312-317).

Notes on the evergreen and the periodically deciduous trees of Java, S. H. KOORDERS (*Forstl. Naturw. Ztschr.*, 7 (1898), No. 11, pp. 357-373, pls. 5).

On the resistance of fir trees to smoke, etc., H. WISLICENUS (*Tharand. Forst. Jahrb.*, 48 (1898), pp. 152-172).

On the shrinking and swelling of wood, D. KITAO (*Col. Agr. Tokyo*, 3 (1898), No. 4, pp. 290-370, pls. 9).—A study of the rate of shrinking and swelling of timber is given, and numerous formulas for determining the same are given.

Investigations in the bark of trees, T. MEEHAN (*Pennsylvania Dept. Agr. Rpt.* 1897, pp. 511-524, figs. 7).—Reprint of Bulletin 29 (E. S. R., 9, p. 812).

Structure of the wood of the Pomaceæ, A. BURGERSTEIN (*Sitzber. Math. Naturw. Cl. K. Akad. Wiss.* [Vienna], 107 (1898), Nos. 1-4, pp. 8-22).

The walnut and its culture, P. MOUILLEFERT (*Prog. Agr. et Vit.*, 30 (1898), No. 52, pp. 774-776, figs. 14).—Gives brief illustrated notes on varieties of walnuts, and notes some of their diseases, the principal of which are *Marsonia juglandis*, *Polyporus sulphureus*, and *Agaricus melleus*.

History of a communal forest, E. PICARD (*Mem. Acad. Sci. Arts et Belles-Lettres Dijon*, 4. ser., 6 (1898), pp. VII + 301).—Describes the Crochères forests and the town of Auxonne.

Concerning the estimation of the quantity of standing timber, K. BÖHMERLE (*Centbl. Gesam. Forstw. Wien*, 24 (1898), No. 12, pp. 519-531).

The nomenclature of the Nebraska forest trees, C. E. BESSEY (*Proc. Nebraska Acad. Sci.*, 6, 1896, pp. 229-237).—The author gives a list of the generally accepted scientific names of the 67 species of trees growing in the State.

SEEDS—WEEDS.

Test of beet seed, E. WALKER (*South Carolina Sta. Bul.* 31, pp. 7-9).—A report is given of investigations made to test the relative value of large and small beet seed. Of the various lots of seed as purchased about 40 per cent were large and plump, while 60 per cent were small, poorly developed, and more or less imperfect. The seed which were grown in shallow boxes were pressed uniformly into the soil and then covered with fine sand. One lot of the seeds was soaked for 5 hours in warm water, while the other was planted dry. The germination of the different lots of large and small beet seed is shown in the following table:

Germination of large and small beet seed.

	Large seed.				Small seed.			
	Third day.	Fifth day.	Eighth day.	Total 8 days.	Third day.	Fifth day.	Eighth day.	Total 8 days.
Dry sown.....	Per cent. 50	Per cent. 25	Per cent. 7	Per cent. 82	Per cent. 23	Per cent. 12	Per cent. 7	Per cent. 42
Soaked.....	64	8	1	72	9	4	5	18

In conclusion the author states that large seed is to be much preferred, since it gives a larger percentage of germination as well as stronger

plants. The experiment also showed that there was no advantage in soaking beet seed prior to sowing, but in this case there was an actual loss amounting to about 18 per cent.

The effect of fertilizers on the germination of seeds, G. H. HICKS (*Proc. Amer. Assoc. Adv. Sci.*, 17 (1898), pp. 428, 429).—A report is made upon a series of tests on the effect of various chemical fertilizers on seeds of wheat, lettuce, radish, and crimson clover. The author's conclusions are as follows:

"One per cent strengths of muriate of potash and sodium nitrate used as fertilizers are very detrimental to the germination of seeds, whether applied directly or mixed with the soil. Fertilizers composed of phosphoric acid or lime are much less injurious to germination than sodium nitrate or muriate of potash, and if not used in excess may be harmless. Commercial fertilizers should not be brought into direct contact with germinating seeds. The effect of treating seeds with chemicals before planting is no index to the action of those chemicals when applied as manures to the soil. The chief injury from chemical fertilizers is effected upon the young sprouts after they leave the seed coat and before they emerge from the soil, while the seeds themselves are injured only slightly or not at all. It is highly improbable that potash, phosphoric acid, nitrogen, or lime used as fertilizers actually favor germination."

On the influence of humus acids on germination, R. TOLF (*Tidskr. Landtmän*, 19 (1898), No. 22, pp. 387-390).—In order to study the effect of free humic and ulmic acids on germination the author filled four germination dishes with sand sterilized by ignition, moistening the sand with distilled water. Four other dishes were filled with raw, wholly undecomposed, but previously finely pulverized peat. The latter was taken 0.5 meter below the surface of a drained marsh and near a ditch, so that its water content was not excessive: the sand in every case contained more water after having been moistened than did the peat. This was a typical Smaland high-marsh peat, made up exclusively of *Sphagnum fuscum* and *Eriophorum vaginatum*, and had a decided acid reaction. Four other dishes were filled with peat in which the free acids had been barely neutralized with chalk.

In each of the 3 sets of germination dishes, prepared as described, series of 100 seeds each of spring wheat, plumage barley, mammoth spring oats, and Probster oats (outer seeds only) were sown, and kept at a temperature of 18 to 20° C. for 5 days. At the end of this period the lengths of the radical and the rootlet of each plant were carefully measured and the plants critically examined. The average results are shown below:

Effect of humus acids on germination.

Kind of seed.	Average length of radical.			Average length of rootlets.		
	Sand.	Raw peat.	Neutralized peat.	Sand.	Raw peat.	Neutralized peat.
	<i>Mm.</i>	<i>Mm.</i>	<i>Mm.</i>	<i>Mm.</i>	<i>Mm.</i>	<i>Mm.</i>
Wheat.....	29.5	13.4	36.3	158.7	36.9	163.1
Barley.....	41.8	20.6	39.7	223.6	77.0	250.6
Rye.....	38.8	23.5	41.4	205.2	59.0	198.7
Oats.....	a 30.4	b 14.1	a 29.9	137.5	45.4	149.5

a All radicals expelled.

b 36 per cent lacked the power to expel the radical.

The deleterious influence of free humus acids on germination is strikingly shown by the results given in the table. The rootlets of grains sown in humus soils invariably presented an abnormal appearance, both as regards position, number, and shape, and the root tips appeared brown, scorched, and shriveled, separated from the rootlet itself by a partition. The proper treatment of humus soils includes liming, admixture of sand, and good tillage.—F. W. WOLL.

The Russian thistle, L. H. PAMMEL (*Iowa Sta. Bul. 38, pp. 24, pls. 4, figs. 3*).—The present bulletin is issued as supplementary to Bulletin 26 of the station (E. S. R., 6, p. 551). Since the previous bulletin was issued sufficient information has accumulated on which to base some opinion as to the aggressive character of the weed. The present distribution in Iowa embraces 48 stations; but the author thinks that on account of the fact that cultivated crops are so extensively grown in the State the weed will never become as noxious as many other species. Notes are given on the character of the plant, its distribution, methods of eradication, and its forage value, together with a partial bibliography of station and department publications relative to it.

Sixth report on Kansas weeds, A. S. HITCHCOCK and G. L. CLOTHIER (*Kansas Sta. Bul. 80, pp. 113-164, pls. 16*).—In Bulletin 57 of the station (E. S. R., 8, p. 409) the authors give a descriptive list with distribution of the weeds of the State, but since that time many notes and observations have accumulated and it is thought desirable to issue a new bulletin showing the distribution of weeds throughout the State. As in the previous bulletin, the distribution of the different species is indicated by maps in which a dot indicates the presence of an authentic specimen from the different counties of the State. In the present bulletin 209 species are described, 80 of which are included in the list designated as bad weeds. While other species than those enumerated may be troublesome in some localities, yet from several years experience it is thought that for the State as a whole the list would be confined to the species enumerated. Of the 80 bad weeds 23 are perennial, 7 biennial, and the remainder annuals, several of which are so-called winter annuals. Of the total list of weeds enumerated 149 species are native to the State, and of the list of bad weeds one-half are native plants, and among these are many of the worst. The distribution throughout the United States of the 80 weeds classed as most troublesome is also given.

The methods by which weed seeds are scattered are discussed at some length, the principal agents mentioned being wind, animals, automatic movements, railroads, and the use of impure grass, grain, and vegetable seeds, etc.

In 1893 a plat 10 ft. square was marked off on the station ground and a record kept of the seedling weeds which were removed from time to time. This has been continued for several years and the record for 1893-1897 is given.

Notes are given on the number of seeds produced by some weeds, the author having determined approximately the number of seeds produced by a single plant of some of the more common weeds. The following table shows the approximate number of seed produced by some of the worst weeds:

Number of weed seed produced by a single plant.

Species.	Number.	Species.	Number.
<i>Portulaca oleracea</i>	69,000	<i>Amarantus albus</i>	14,000
<i>Abutilon avicenna</i>	31,900	<i>Amarantus blitoides</i>	155,000
<i>Hibiscus trionum</i>	43,300	<i>Acnida tuberculata</i>	945,000
<i>Ambrosia artemisiifolia</i>	23,100	<i>Cyceloma platyphyllum</i>	357,600
<i>Xanthium canadense</i>	9,700	<i>Euphorbia marginata</i>	21,900
<i>Bidens frondosa</i>	10,500	<i>Panicum sanguinale</i>	89,600
<i>Martynia proboscidea</i>	8,000	<i>Setaria glauca</i>	113,600
<i>Salvia lanceolata</i>	1,900	<i>Cenchrus tribuloides</i>	42,700
<i>Amarantus retroflexus</i>	85,000	<i>Eragrostis major</i>	140,000

The authors have made some investigations relative to the fertilization of flowers and have found that the following are dependent on insect visits: *Portulaca oleracea*, *Ipomœa hederacea*, *I. purpurea*, *Solanum rostratum*, and *Euphorbia maculata*. The following species are self-fertile: *Abutilon avicenna*, *Hibiscus trionum*, *Ira ciliata*, *Bidens frondosa*, *Amarantus retroflexus*, *Acnida tuberculata*, *Chenopodium album*, *Phytolacca decandra*, *Polygonum pennsylvanicum* (seed smaller than average), *Euphorbia marginata*, *Panicum sanguinale*, *Setaria glauca*, and *Eragrostis major*.

The authors discuss the subject of the eradication of weeds and give a list with descriptive notes of 209 species.

Massachusetts weeds, G. E. STONE (*Agr. Massachusetts, 1897, pp. 268-277*).—A popular article on the dissemination, distribution, and eradication of weeds.

A new wild lettuce from New England, B. L. ROBINSON (*Rhodora, 1 (1899), No. 1, pp. 12, 13, pl. 1*).—The author describes *Lactuca morssii* from Massachusetts. It somewhat resembles *L. canadensis* and *L. leucophaea*.

Matricaria discoidea in eastern Massachusetts, W. H. MANNING (*Rhodora, 1 (1899), No. 1, p. 18*).—The occurrence of this weed at several stations is noted and it is said to be apparently driving out the common mayweed, *Anthemis cotula*.

On the destruction of orobanche on clover, A. LONAY (*Jour. Soc. Agr. Brabant-Hainaut, 1898, No. 38*).

DISEASES OF PLANTS.

Report of the botanist, G. E. STONE and R. E. SMITH (*Massachusetts Hatch Sta. Rpt. 1897, pp. 47-70, pls. 2*).—The authors give a brief review of the work conducted during the past year and report more at length upon some of the particular lines of investigation.

The causes of the failure of the potato crop of 1897 were investigated. Among other causes may be mentioned the extremely wet condition of the soil at planting time, which is thought to have induced the rotting of the stems of the young plants just below the ground. The authors

do not consider this a specific disease of the potato nor do they think any treatment necessary. About the middle of July several extremely hot, sunny days following a long rainy period occurred, and in many potato fields on low ground the plants began to wilt. Investigation of the plants showed that there was no one organism, with possibly the exception of bacteria, affecting the plants, but there was a general rotting resulting from the wet condition of the soil and the consequent low vitality of the plants. This trouble was considered to be due to abnormal weather conditions, and when the potatoes had reached a marketable size the authors recommended digging them to prevent decay.

In August the potato blight or rot due to *Phytophthora infestans* appeared and spread extensively.

The drop of lettuce caused by *Botrytis* sp. is discussed at some length, and suggestions are given for the sterilization of soil in greenhouses by steam or other means. Steam sterilization is thought to be the most promising. Various methods of treatment for this disease are being investigated, and it is said to be desirable to ascertain how deep the soil should be sterilized in order to keep down the fungus.

Notes are given on asparagus rust and the possibility of checking it by cutting and burning the plants is discussed. Several instances are cited in which cutting, which was extensively practiced in the season of 1897, seemed to be almost entirely without effect, the rust appearing quite badly on the second growth. The experience of another season is said to be necessary to demonstrate the effect and seriousness of this disease.

The authors briefly discuss the fire blight of pear, quince, and apple due to *Micrococcus amylovorus*, quince rust caused by *Gymnosporangium claripes*, the brown rot of stone fruits due to *Monilia fructigena*, and chrysanthemum rust caused by *Puccinia tanacetii*. In reference to the last-named disease they state that great care should be exercised in selecting cuttings from vigorous plants unaffected by rust, and that spraying with Bordeaux mixture or a potassium sulphid solution will probably prove profitable. Several other diseases affecting the leaves of chrysanthemums are noted, but the discoloration of the leaves affected by the rust will distinguish them. In the case of the rust there is a production of numerous small pustules on the under side of the leaf which contain a dark red powdery substance similar to carnation rust.

A disease of the cultivated geranium is briefly described, which is characterized by the leaves turning yellow in small spots which gradually increase in size, the leaf tissue dying away at these points. The dead spots spread until finally the leaves lose their vitality completely. All varieties are equally affected. The disease is reported from several localities in the State. The injury seemed to be the result of an attack of some fungus, but investigation of infected leaves failed to reveal any specific organism. Plants sprayed with

Bordeaux mixture gave no appreciable immunity. The authors do not consider this a genuine disease, but state that it is probably due to low vitality and hindered growth, caused by excessive moisture.

Brief notes are given on leaf blights of native trees. Among those described are the following: Leaf blight of sycamore (*Glœsporium nerisequum*), leaf blight of butternut (*G. juglandis*), leaf spot of chestnut (*Septoria ochroleuca*), and leaf spot of wild black cherry (*S. cerasiua*).

A bacterial disease of beets, PRILLIEUX and DELACROIX (*Compt. Rend. Acad. Sci. Paris*, 127 (1898), No. 6, pp. 338, 339).—For several years there has been noticed in the north of France and in the vicinity of Paris a disease of beets, to which the name "yellows" (*jaunisse*) has been given. This disease seems to appear on soil where seed beets have been grown, and makes its appearance between the 1st and 15th of July. At first the leaves lose their normal turgescence, the petioles become less rigid, and the tip of the leaf turns down. At the same time the leaves become finely variegated green and white, as is the case in the mosaic disease of tobacco. This appearance is more noticeable by transmitted light, the discolored portions, especially in the young leaves, being translucent. With the progress of the disease the discolored spots coalesce and the leaf dries up; at this time the color varies from yellow to gray. When plants are severely attacked the roots do not increase much in size, although retaining their normal sugar content, and the total loss of the crop is about 50 per cent. If the diseased beets are planted for seed in the spring, the leaves which appear will show the pathological characters which have been enumerated. Under the microscope the diseased areas show great numbers of short, curved bacteria, which rapidly render the liquid contents of the cell turbid. The chlorophyll bodies of the cell are discolored and the granules in the cells become more refractive and are more apparent than in sound leaves. When mother beets are attacked by the bacteria, not only the leaves but the floral bracts and calyx are attacked, and it seems probable that the bacteria are able to persist, probably in the state of spores, in the fruit of the beet.

Experiments have been conducted to test the artificial infection of beets with this disease with marked success. Three rows of beets were seeded in sterilized soil and transplanted to a soil in which beets had not been grown. One row was watered with a diluted pure culture of the bacteria and in a few days the characteristics of the disease appeared, while the others remained absolutely unaffected.

In the second experiment dried leaves from diseased plants were powdered and mixed with the soil in the garden in April. Young beets were transplanted to the soil and, except when planted in the soil receiving the powdered leaves, there was no appearance of disease. The authors consider it established that this disease is due to bacteria, and further study under the direction of the minister of agriculture is contemplated.

Concerning a root disease of wheat, L. MANGIN (*Compt. Rend. Acad. Sci. Paris*, 127 (1898), No. 5, pp. 286-288).—The author gives a report on a disease of wheat known in France since 1878, which has been generally attributed to *Ophiobolus graminis* (E. S. R., 9, p. 1057). This fungus is said to develop principally on the leaf sheaths and rarely on the culm or roots. The author states that he has found associated with it *Leptosphaeria herpotrichoides*. The effect of both these fungi on the wheat plant was shown, and their parasitism seems well established. Other species of fungi that have from time to time been reported as associated with them are said to be saprophytic, and are not directly concerned in producing the disease in question. A report is given on a series of inoculation experiments carried on with the fungi, from which it appears that both parasites are found in the lower internodes, while *Ophiobolus* sometimes occurs on the roots. They are capable of producing diseased conditions of the culm, weakening it and greatly reducing the total harvest. The rigidity of the culms is influenced somewhat differently by the different fungi, the *Leptosphaeria* probably causing the most damage. As a result of the invasion of the fungi the culms take a peculiarly twisted condition, and the harvest is diminished not only on account of the presence of the parasite, but because the twisting restricts to some extent the circulation in the plants and exposes the weakened plants to attacks of numerous parasites and saprophytes.

The asparagus rust: Its treatment and natural enemies, B. D. HALSTED (*New Jersey Stas. Bul.* 129, pp. 20, pls. 2).—A brief sketch is given of the history and distribution of asparagus rust which before 1896 was only known to occur in this country in California. Since that time it has spread extensively and it now seems to occur throughout New England and the Atlantic Coast region as far south as South Carolina. The interior and western part of the United States seems as yet to be free from the rust and it has not been reported for a number of years in California.

When the asparagus field is badly affected with the rust, the general appearance of the plants is that of unusual early maturity. Instead of the healthy green color the plants are of a brownish hue, as though insects had sapped them or frost destroyed their vitality. A close examination shows the characteristic appearance of the rust, and all its stages are borne upon the same host.

Experiments were conducted to test the value of spraying plants with Bordeaux and similar fungicides for the prevention of the rust. A number of plants were selected and 10 applications given at a total cost of \$4.59, or at the rate of \$21.76 per acre.

The result of the application of fungicides seemed to indicate a reduction of the disease amounting to about 25 per cent. The author recommends the autumn treatment of the fields, which consists of burning old brush, either as it stands in the field or by cutting and burning in

piles. The latter method, however, is thought to be hardly as efficient as the former on account of the fact that many spores will be scattered in the cutting and piling. It is thought that a thin coat of lime sprinkled over the ground and left there during the winter will also prove beneficial in destroying those spores which may have found lodgment on the soil.

Two fungus enemies are described which attack the asparagus rust and may, to some extent, help hold it in check. These are *Darlucium* and *Tubercularia persicina*.

The author gives briefly a summary of the literature relating to asparagus rust in the United States.

Briefly summarizing the conclusions, it is stated that the asparagus fungus (*Puccinia asparagi*) was described as early as 1805 and is generally distributed throughout Europe. Aecidial, Uredo, and Teleutosporic forms are all found on the asparagus plant. Spraying experiments with Bordeaux and similar fungicides reduced the amount of rust about one-fourth. Among the varieties tested Palmetto proved less susceptible than others. The pistillate plants also appear less subject to attack than the staminate ones. This rust is found on other species of asparagus, but so far is not known to occur on any wild plants or weeds other than asparagus.

Experiments in combating the rose rust in 1898, K. MOHR (*Rosen Ztg.*, 13 (1898), No. 5, pp. 79, 80).—The occurrence of the rose rust on quite a number of varieties of roses during the summer of 1898, led the author to conduct a series of experiments for the prevention of the disease. It was successfully combated by spraying the plants with a mixture composed of 9 liters of limewater and $\frac{3}{4}$ liter Sulfurin. The limewater was formed by slaking quicklime and thoroughly stirring it before using. After mixing with the Sulfurin the mixture is allowed to settle and the clear liquid is sprayed upon the plants. Investigations made from time to time during the season on some of the more susceptible varieties showed that where the plants had been sprayed no rust was present, while upon the unsprayed ones the disease was very abundant. In spraying the roses particular pains must be taken to spray both surfaces of the leaf, as well as to apply it thoroughly to the stems of the plants. The author states that the same mixture is also very beneficial in combating the rust of mallows (*Puccinia malvacearum*).

Concerning the adherence of copper compounds which are used in combating diseases of the grape, G. M. GUILLON and G. GOUIRAND (*Compt. Rend. Acad. Sci. Paris*, 127 (1898), No. 4, pp. 254-256; 11, pp. 423, 424).—The authors have investigated the subject of the adherence of different fungicides, making a study of the following: (1) Bordeaux mixture, composed of 2 per cent of copper sulphate and sufficient lime to render the mixture slightly alkaline; (2) the same with the addition of 1 per cent molasses; (3) the same with the addition of 0.3 per cent gelatin; (4) mixture of 2 per cent copper sulphate and 3

per cent carbonate of soda: (5) a solution of 2 per cent copper sulphate and 3 per cent of bicarbonate of soda; (6) 2 per cent copper sulphate and 3 per cent soap; (7) 2 per cent copper sulphate and 3 per cent carbonate of potash; (8) 2 per cent copper sulphate and 3 per cent carbonate of ammonia; (9) eau celeste, to which sufficient ammonia is added to render the solution slightly alkaline; (10) 2 per cent solution of copper acetate, and (11) neutral acetate of copper.

The method of distinguishing the adherence of these different fungicides was to place small quantities of the liquid on glass plates which had been previously washed with alcohol, and after drying them in the sun subject them to an artificial rain; the liquid remaining on the plate was tested for copper immediately after its deposit, also 2 and 24 hours later. At the expiration of 24 hours the Bordeaux mixtures were the most adherent, followed closely by the mixture composed of copper sulphate and carbonate of potash and eau celeste. Some of the other fungicides had been completely washed off at the end of 24 hours.

The experiments were repeated, the plates being exposed to natural rain with results analogous to those above. From the authors' experiments it seems that acid Bordeaux mixture is less adherent than basic, and basic still less than neutral Bordeaux mixture. The same applies to fungicides containing carbonate of soda. When molasses is added to the mixture in general they are less adherent, and the more molasses added the less the adhesive power. The same applies equally to gelatin.

In a series of experiments reported later the authors tested the adherence of the same fungicides on grape leaves under the same conditions as previously given. In the case of the latter experiments they concluded that in general fungicides as used were less adherent than those prepared under the earlier formulas. The difference in the case of the adhesive power of Bordeaux mixture was not very great, but in the case of those fungicides containing soda, soap, or ammonia, it was greatly affected by the method of preparation used. In conclusion the authors state that fungicides to be most adherent to grape foliage, especially those containing soda or soap, ought to be employed immediately after their preparation.

Based upon their adhesiveness the fungicides may be arranged in the following order: (1) those containing soap; (2) bicarbonate of soda; (3) carbonate of soda; (4) Bordeaux mixture, carbonate of potash, eau celeste, and acetate of copper; (5) gelatin; (6) molasses, and (7) neutral acetate of copper. In general all these fungicides are most adherent the nearer neutral they are made.

The brulure of flax, E. MARCHAL (*Bul. Soc. Belg. Micros.*, 22 (1898), pp. 125, 126).—This disease, which results in the etiolation of the plants, is said to be due to *Asterocystis radialis*.

A clover fungus (*Jour. Bd. Agr. [London]*, 5 (1898), No. 1, pp. 37-50, figs 2).—Illustrated notes are given of *Sclerotinia trifoliorum*.

Protection against canker of white fir, HECK (*Forstl. Naturw. Ztschr.*, 7 (1898),

No. 10, pp. 344-347).—Notes the distribution and methods of attack and suggests means for the prevention of *Agaricus adiposus* and *Polyporus hartigii*.

Notes on apple canker, W. PADDOCK (*Science, n. ser.*, 8 (1898), No. 206, pp. 836, 837).—It is stated that *Sphaeropsis malorum* is in all probability parasitic on the wood of the pear and quince as well as upon the apple. Inoculations made from cultures from the 3 kinds of wood produced diseased fruits in every case.

Some important pear diseases, B. M. DUGGAR (*New York Cornell Sta. Rpt. 1898*, pp. 596-627, figs. 16, dgm. 1).—A reprint of Bulletin 145 of the station (E. S. R., 10, p. 450).

The lily disease (*Amer. Gard.*, 19 (1898), No. 210, p. 893).—The views of Peter Barr on the cause of the lily disease are given, in which it is attributed to weakness of plants, due to exhausted condition of Bermuda soils where bulbs are grown. American and Holland bulbs are expected to be free from this trouble.

A new disease of cultivated palms, W. TRELEASE (*Rpt. Missouri Bot. Gardens*, 9 (1898), p. 159, fig. 1).—*Erosporium palmivorum*, a new species by Saccardo, is figured and described as the cause of a disease of *Phoenix canariensis*, *P. tenuis*, and *P. reclinata*.

Fungus and insect pests of the red beech in the Alsacian forests, STROHMEYER (*Forstl. Naturw. Ztschr.*, 7 (1898), No. 9, pp. 316-319).

Distribution of potato diseases in Germany, FRANK (*Deut. Landw. Presse*, 25 (1898), No. 32, pp. 247, 248; abs. in *Bot. Centbl.*, 76 (1898), No. 1, pp. 26, 27).—Diseases due to *Phytophthora*, *Rhizoctonia*, *Phellomyces*, and the bacterial diseases are said to be generally distributed throughout the country. *Fusarium* is not found in Brandenburg nor in the Kingdom of Saxony. Nematodes are reported as particularly destructive in 9 states and provinces. A considerable variation in resistance of varieties to disease is also reported.

Some observations bearing upon the symbiotic mycoplasma theory of grain rusts, H. L. BOLLEY (*Proc. Amer. Assoc. Adv. Sci.*, 47 (1898), p. 408).—The author reviews the work of Eriksson relative to the rusts of cereal grains and other grasses. He dissents from the view given by Eriksson that there is any indication of a mycoplasma infection. The author gave an outline of experiments in which he grew cereals to maturity in rust-proof cages without any infection whatever, although every plant close by bore numerous pustules. Incidentally it is stated that the germ tubes of the uredo-spores may enter not only by way of the stomata, but also directly through the cuticle of wheat and oat plants.

The smuts and blights of cereals, E. THOMAS (*Jour. Soc. Agr. Brabant-Hainaut*, 1898, No. 38).

Chrysanthemum rust, G. ABBEY (*Jour. Hort.*, 50 (1898), No. 2611, pp. 284, 285, figs. 2).—The uredo and puccinia forms of this rust are figured and described. The author thinks the method resorted to in forcing the plants is largely responsible for the disease. Bordeaux mixture is recommended as an efficient fungicide. Washing the plants with a permanganate of potash solution is also mentioned as an effective treatment.

Twig galls of the pine, K. VON TUBEUF (*Forstl. Naturw. Ztschr.*, 7 (1898), No. 9, p. 321).

Parasites of the willow, E. CROUZEL (*Les parasites du saule. Paris: Soc. d'Edit. Scientifiques*, 1898, pp. 36).—Treats briefly of the principal fungus and insect pests of willows, with means for their prevention.

Some coffee pests, A. ZIMMERMANN (*Teysmannia*, 9 (1898), No. 9-10, pp. 402-421).—In an address before the Coffee Congress at Malang the author mentioned some of the more destructive enemies of coffee culture, among them being nematodes, *Tylenchus coffea* being especially troublesome.

The influence of potash fertilizers on "beet sickness," M. HOLLRUNG (*Ztschr. Ver. Deut. Zuckerind.*, 1898, pp. 343; abs. in *Bot. Centbl.*, 76 (1898), No. 7, pp. 243, 244).—The author concludes, from an extensive series of experiments, that potassium carbonate, and especially potassium magnesium carbonate, exert a favorable influence in correcting "beet sickness" of soils.

ENTOMOLOGY.

House flies, L. O. HOWARD (*U. S. Dept. Agr., Division of Entomology Circ. 35, 2. ser., pp. 8, figs. 6*).—The difference between house flies and several related species is briefly pointed out. The eggs, about 120 for each individual, are usually laid upon horse manure. One-fourth pound horse manure, taken from a pile of manure in August, contained 160 larvæ and 146 puparia. Larvæ are not found in perhaps the greater part of ordinary horse-manure piles, but in one case about 200 puparia were found in less than 1 cu. in. of manure.

“The periods of development were found to be about as follows: Eggs from deposition to hatching, one-third of a day; hatching of larva to first molt, 1 day; second molt to pupation, 3 days; pupation to issuing of the adult, 5 days; total life round, approximately, 10 days. There is thus abundance of time for the development of 12 or 13 generations in the climate of Washington every summer.”

Experiments were conducted during 1897 and 1898 to determine whether a manure pile could be treated to stop the breeding of house flies.

“It was found to be perfectly impractical to use air-slaked lime, laud plaster, or gas lime with good results. Few or no larvæ were killed by a thorough mixing of the manure with any of these three substances. Chlorid of lime, however, was found to be an excellent maggot killer. Where 1 lb. of chlorid of lime was mixed with 8 qt. of horse manure 90 per cent of the maggots were killed in less than 24 hours. At the rate of a quarter of a pound of chlorid of lime to 8 qt. of manure, however, the substance was found not to be sufficiently strong. [This, however, is considered too expensive for practical use.] It was found that 8 qt. of fresh horse manure sprayed with 1 pt. of kerosene, which was afterwards washed down with 1 qt. of water, was thoroughly rid of living maggots. Every individual was killed by the treatment.”

This remedy did not prove entirely satisfactory when employed on a large scale. An attempt to prevent the breeding of house flies in a pile of manure was begun early in April, 1898, and continued for some time.

“While undoubtedly hundreds of thousands of flies were destroyed in the course of this work, it was found by the end of May that it was far from perfect, since used at an economical rate the kerosene could not be made to penetrate throughout the whole pile of manure, even when copiously washed down with water. A considerable portion of house-fly larvæ escaped injury from this treatment, which at the same time was found, even at an economical cost, to be laborious, and such a measure in fact as almost no one could be induced to practically adopt.”

A measure which proved very successful was to place the manure collected each morning in a closet, the window of which was provided with a wire screen, and to scatter a small shovelful of chlorid of lime over it.

House ants, C. L. MARLATT (*U. S. Dept. Agr., Division of Entomology Circ. 34, 2. ser., pp. 4, figs. 3*).—The habits, life histories, and characteristics of the red ant (*Monomorium pharaonis*) and the pavement ant (*Tetramorium cespitum*) are given and other species are noted.

The possibility of driving ants away by the use of gum camphor is

noted. Where the nests can be located, whole colonies may be destroyed by pouring an ounce or two of carbon bisulphid into a number of holes made in the nest with a stick and promptly closing the holes with the foot.

“Whenever the nests of any of these ants can not be located, there is no other resource than the temporary expedient of destroying them wherever they occur in the house. The best means of effecting this end is to attract them to small bits of sponge moistened with sweetened water and placed in the situations where they are most numerous. These sponges may be collected several times daily and the ants swarming in them destroyed by immersion in hot water. It is reported also that a sirup made by dissolving borax and sugar in boiling water will effect the destruction of the ants readily and in numbers. The removal of the attracting substances, wherever practicable, should always be the first step.”

The true clothes moths, C. L. MARLATT (*U. S. Dept. Agr., Division of Entomology Circ. 36, 2. ser., pp. 8, figs. 3*).—The case-making clothes moth (*Tinea pellionella*), the webbing or southern clothes moth (*Tineola biselliella*), and the tapestry moth (*Trichophaga tapetzella*) are described and their life histories and habits are briefly given. The remedies usually employed are noted, namely, beating, shaking, or brushing the articles affected, exposing them to air and sunlight, the use of various repellants, such as tobacco, camphor, naphthaline, cedar chips, tarred paper, etc. Articles which are free from the insects may be kept so by inclosing them in tight bags of cotton or linen cloth or strong paper. Cold storage can be successfully used to prevent injury from clothes moths. Tests made at Washington demonstrated that a temperature maintained at 40° F. renders these insects dormant and is thoroughly effective. The larvæ are not killed even at a steady temperature of 18° F., but an alternation of a low temperature with a comparatively high one invariably results in their death.

The larger apple-tree borers, F. H. CHITTENDEN (*U. S. Dept. Agr., Division of Entomology Circ. 32, 2. ser., pp. 12, figs. 3*).—The round-headed apple-tree borer (*Saperda candida*), the spotted apple-tree borer (*S. cretata*), and flat-headed apple-tree borer (*Chrysobothris femorata*) are described and their distribution, food habits, life history, methods of attack, and natural enemies are given.

The methods of controlling the round-headed apple-tree borer are to practice clean culture, cut the larvæ out of the tree, kill them by applying kerosene wherever their castings are seen protruding through the bark, or prevent their entrance by means of impenetrable substances, such as paper and hydraulic cement, or by repellant washes made from fish oil or soft soap, with the addition of caustic potash or washing soda carbolated with carbolic acid.

The remedies are the same for the spotted and flat-headed apple-tree borers as for the round-headed borers, except that for the flat-headed borer the coverings and washes should be applied farther up the tree trunks and branches, and that trap wood may be used. It is suggested that limbs and trunks of newly felled trees which the borers attack,

such as oak, maple, and young fruit trees, be distributed on the outskirts of the orchard, where they should be freely exposed to the sun so that the beetles will deposit their eggs on them. This trap wood should then be destroyed before the beetles emerge the following spring.

The peach borer—experiments with hydraulic cement, J. B. SMITH (*New Jersey Stat. Bul.* 128, pp. 28, figs. 7).—The peach-tree borer (*Sanninoidea exitiosa*) is well known to peach growers and causes considerable loss annually. In general orchards on light soils are said to suffer more than those on heavy soils, while in some stony orchards the trees are almost exempt. Many methods of prevention, some of them effective, have been proposed to prevent injury, and the author determined upon a series of experiments in 1897 partly to test some of the applications themselves and partly to discover the reason for contradictory results. It was discovered at the outset that there was a great lack of definiteness in our knowledge of the life history of the insect and that statements heretofore made, while mostly true, were lacking in completeness. On this account a rather full study of the early stages of the insect was made and the earlier published accounts of Say and others reviewed.

It appears that the larva becomes full grown some time between the last of May and the first of August. It forms a cocoon of sawdust, excrement, and silk, in which it changes to a pupa. The moths begin to emerge some time during the latter part of June and continue until the first days of September. The sexes are produced in about equal numbers, copulate soon after issuance, the female beginning to lay eggs immediately thereafter, placing them anywhere on the trunk and even on the branches 5 ft. or more from the ground. The eggs never seem to be deposited at the surface of the ground or very close to it, but will mostly be found 6 to 18 in. above the ground. The adult life is short, perhaps only a day or two, and the female lays in that time between 500 and 600 eggs. The egg period is said to be probably 7 to 10 days and the young larvæ may crawl or bore almost anywhere, but sooner or later work their way to the base of the tree, where they may be found from the surface to 18 in. underground. The winter is passed in the larval stage in the tree and growth is resumed in the spring until ready for pupation. About the middle of July all stages, from egg to adult, may be found in a badly infested orchard. These dates apply only to New Jersey and Long Island.

A rather comprehensive description of the insect is given in which it is stated that the caterpillars are white, except the head and part of the first segment, which are yellowish and become brown. Along the sides is a series of almost round yellowish dots, and scattered over the surface, arising from definitely arranged smooth warts, are short, stiff, bristly hairs, more prominent in young than in the mature larva. The anal end of the larva is also brown. The caterpillar changes little

in appearance as it grows, but becomes stouter and is known as a fat, white worm or grub. The larvæ from which males are produced are smaller than those producing females. The cocoon and pupa are described as well as the mature insect. The male moth is said to be of a steel-blue, almost black color, with a narrow yellow collar and narrow yellow bands on the abdomen, giving it a decided wasp-like appearance. The female is larger, more heavily built, bluish in color, and has a broad orange band about the middle of the abdomen by which it can be readily recognized.

The injuries caused by the borers are described. No peach tree seems to be safe from attack. When the borers once get into the tree there is nothing to do but cut them out. The principal treatment is a preventive one. The experiments were made in the protection of the trees with newspapers, waxed heavy paper, heavy manila wrapping paper, tar paper, tile tree protectors, wooden box protectors, hydraulic cement and skim milk, hydraulic cement and water, Bordeaux mixture with an excess of lime, and wrapping with wire netting. All covers were extended at least 12 in. above and 2 in. below the ground. The experiments were carried out in a number of orchards and the detailed reports are given. The experiments show that wrapping the trees with double thickness of newspapers so that at least 15 in. of the trunk above ground is covered is one of the most efficient methods. When the wrappings are taken off, which should be done about the middle of September, the trees should be closely examined, and if any borers have made their way in above the paper they should be cut out. The paper wrapping should be put on the trees every year not later than the first week in June. In tying on the papers too strong or stiff twine should not be used, since peach trees grow rapidly and may become girdled unless the twine is somewhat yielding and breaks under a moderate strain.

The experiments conducted with hydraulic cement were quite successful, and the author recommends a mixture of cement and skim milk to be applied to the tree trunks. This forms a continuous coating that will remain in good condition during the entire summer. It does not appear to produce any injury whatever, is impenetrable to young larval insects, and such a surface would not be selected by the adult for oviposition. The coating is said to be sufficiently elastic to admit of moderate growth and quite brittle enough to break readily from efforts of any insects to get out from beneath the bark. It would not therefore prevent the exit of borers that are already working in the tree, but would keep out young larvæ attempting to get in.

The author thinks probably this cement added to some of the soap washes used by fruit growers would improve their lasting qualities. The water and cement mixture was so far inferior to that made with skim milk that its use is not recommended. In all cases the cement should be broken up with a stiff brush when the danger season is over.

On young trees it should not be put on until necessary or kept on longer than required, so that the bark may develop normally. On old trees it is said to make little difference when the application is made.

The striped cucumber beetle, F. H. CHITTENDEN (*U. S. Dept. Agr., Division of Entomology Circ. 31, 2, ser., pp. 7, figs. 2*).—This is a popular circular giving general appearances and nature of attack of the striped cucumber beetle, its food plants, life history and habits, and remedies for it. The injury is due to the "direct attack by the beetles to the plant above ground; indirectly to the beetles as transmitters of disease germs; and to the larvæ working upon the roots underground." The larvæ are thought to be restricted to cucurbitaceous plants but the beetles feed on many cultivated plants such as beans, peas, apple blossoms, ripe apples; the leaves, silk, pollen, and unripe kernels of corn, and on such wild plants as golden-rod, aster, the flowers of choke cherry, juneberry, cherry, and other rosaceous plants; the stamens, pistils, and ray flowers of sunflowers, and probably other composites. The wild cucumber (*Echinocystis lobata*) is not only attacked by the beetles but is probably also a larval food plant. Among the remedies noted are covering the young plants, early planting, clean culture, stimulating growth, the use of trap plants, slaked lime, arsenites with ashes, dust, or plaster, and plaster saturated with kerosene or turpentine, etc.

Three injurious insects, A. L. QUAINANCE (*Florida Sta. Bul. 45, pp. 53-74, pls. 3*).—The author describes the bean-leaf roller (*Eudamus proteus*), the corn delphax (*Delphax maidis*) and the canna-leaf roller (*Hydrocampa cannalis*).

The bean-leaf roller has been quite destructive to beans throughout the State. The larvæ feed upon the leaves, eating holes in them or feeding upon their edges. Descriptions are given of the different stages in the life history of this insect and observations are given on some of the facts established in studying its life cycle. The larvæ were easily bred in the insectary and invariably pupated within a folded leaflet or several leaflets fastened together. The author states that notwithstanding the fact that diligent search has been made he has been unable to find a single pupa in the field and he suspects that this state may possibly be passed in the soil. Considering the life cycle as averaging about 30 days, 8 or 9 broods of this insect would occur during the year, since they appear early in March and at the latitude of the station continue breeding usually through December. The different broods are not distinct as eggs, young and old larvæ, and adults are found in considerable abundance by early summer. In the more southern parts of the State it is believed that the breeding is continuous throughout the year. Both the larvæ and adults move about freely at all times of the day. The use of Paris green in the proportion of 1 lb. to 150 gal. of water, to which is added 1 lb. of quicklime has proved very efficient in treating for this insect and this insecticide does not destroy the foliage of the plant.

The corn delphax has been observed in several localities in the South

and has proved very destructive to corn. It is a sucking insect, feeding on the sap which it sucks from the leaves and stalks, causing them to turn yellow and frequently die. The insect in all its stages is injurious to its host. The eggs are deposited mainly along the midribs of the leaves, in the loose cellular tissue just below the epidermis. In the earlier stages the insects seem to prefer the leaf sheaths or a protected part of the leaf, as where one leaf overlaps another, but after the fourth phase in their life cycle, they occur somewhat promiscuously on the leaf and stem. The egg state is continued for 17 days. From the nymphal state it passes through five stages, which makes the life cycle about 60 days. Technical descriptions are given of the different stages of the insect, and treatment suggested. Where plants are badly infested it will probably be best to burn them. The exact natural food of the insect is not known, but it is believed to be confined probably to grasses, and it seems safe to replant an infested field with almost any other crop than corn or allied crops.

The canna-leaf roller has been noted for the past 3 years in the vicinity of the station and has occasioned serious damage to these plants. The leaves are either rolled up from one side by the larvæ or, as is more frequently the case, the younger leaves are fastened before they have unrolled to any extent. The caterpillars feed in the rolled up leaves, eating out the soft tissue. Notes are given upon the life history of this insect, together with technical descriptions of its various phases. The canna-leaf roller, the author states, can doubtless be controlled by carefully cleaning off and burning the dead plants and trash from the beds during the winter season. The most of the pupæ and larvæ, which pass the winter in these leaves and trash, will thus be destroyed. The rolled up leaves should be watched for in the spring and cut off and burned.

Remedial work against the Mexican cotton-boll weevil, L. Ó. HOWARD (*U. S. Dept. Agr., Division of Entomology Circ. 33, 2. ser., pp. 6*).—Work done in Texas by C. H. T. Townsend, when a field agent of the division showed that the cotton-boll weevil is attracted by sweets. Preliminary experiments with confined weevils suggest treatment of overwintered beetles with a mixture of molasses, with one-fourth its volume of arsenic, applied to the volunteer stalks of cotton in the spring when the leaves are beginning to appear, and treatment of young planted cotton with a spray made of white arsenic, 1½ to 2 oz. boiled in 1 gal. of water until thoroughly dissolved, mixed with 2 or 3 gal. of cheap molasses and diluted with 40 gal. of water.

“The careful study of the weevil damage in Texas conducted by the division during the last 3 or 4 years has demonstrated that the prevention of weevil damage is more a question of the adoption of a proper system of cultivation than of remedial or preventive schemes, such as the use of poisons. In other words, it is admitted by intelligent planters everywhere that the presence of the weevil is made possible by a system of culture which admits of the existence of volunteer cotton, and if the methods followed are such as to prevent such volunteer growth the weevil will rarely, if ever, be troublesome.”

An account is given of the working of a machine for the collection and destruction of infested cotton-bolls and weevils.

On the effect of soil treatment for the prevention of insect injuries, J. RITZEMA-BOS (*Ztschr. Pflanzenkrankh.*, 8 (1898), No. 2, pp. 113-121).—The author reports on the use of benzin and carbon bisulphid injected into the soil for the prevention of injuries caused by nematodes and various root-eating insects. The form of injector is described and notes are given from correspondence with quite a number of individuals relative to the use of the same. It is shown that by the injection of benzin and carbon bisulphid into the soil all the injurious insects are destroyed for a considerable distance. An experiment is reported in which carbon bisulphid was injected into the soil of an oat plat, with the result that there was a very material increase both in straw and grain. It is said that oats could not be grown in this soil heretofore on account of the serious attacks of nematodes.

The bee from the earliest times to the present, A. GMELIN (*Die Biene von der Urwelt bis zur Neuzeit*. Stuttgart: E. Ulmer, 1899, pp. 83, figs. 11).—This is a short review of the development of apiculture. It is reprinted from Witzgall's "Das Buch von der Biene."

Apiculture by simple methods, R. HAMMELL (*L'Apiculture par les méthodes simples*. Paris: G. Carré et Naud, 1898, pp. 338, pls. 4, figs. 102).

Tables for the determination of New Mexican bees, T. D. A. COCKERELL (*Bul. Sci. Lab. Denison Univ.*, 9 (1898), No. 3, pp. 41-73).

Injurious insects and diseases of the year, P. H. ROLFS (*Proc. Florida Hort. Soc.*, 1898, pp. 85-93, figs. 15).—Notes are given on the bean-leaf roller, canna-leaf roller, strawberry pamera, the status of the San José scale and its fungus parasite, bacterial tomato blight, its infection and prevention, and a fungus blight of tomatoes.

Biological studies of plant lice, A. MORDWILKO (*Arb. Zool. Lab. Univ. Warschau*, 1898, pp. 20, 27; *abs. in Zool. Centbl.*, 5 (1898), No. 23-24, pp. 808-812).—Treats of the migration, some of the phases of the life history, polymorphism, etc., of plant lice.

Asphondylia rübsaameni, n. sp., KERTESZ (*Terevesctr. Fuz.*, 21 (1898), pp. 248-253, fig. 1; *abs. in Zool. Centbl.*, 5 (1898), No. 18-19, p. 618).—The author describes this new insect from stunted fruits of *Ferula heuffelii*.

The black peach aphid, W. G. JOHNSON (*Maryland Sta. Bul.* 55, pp. 137-140, figs. 4).—The black peach aphid (*Aphis prunicola*) has appeared in some sections of Maryland in unusual numbers. The bulletin calls special attention to the work of this insect and suggests remedies. Of the remedies tried the author has found kerosene emulsion the most successful.

The codling moth, M. V. SLINGERLAND (*New York Cornell Sta. Rpt.* 1898, pp. 421-488, pl. 1, figs. 21).—A reprint of Bulletin 142 of the station (E. S. R., 10, p. 460).

Cutworms in young tobacco, W. G. JOHNSON (*Maryland Sta. Bul.* 55, pp. 141-144, figs. 4).—A popular account of the habits of some cutworms which attack young tobacco, with suggestions as to remedies. Directions are given for the preparation and use of a poisoned bait made of 50 lbs. wheat bran, 2 qt. molasses, 1 lb. Paris green, and water to make a thick mash.

The elm-leaf beetle in New York State, E. P. FELT (*Bul. New York State Mus.*, 5 (1898), No. 20, pp. 34, pls. 6, figs. 6).—The life history of *Galerucella luteola* is given, together with notes on its distribution in the State, natural enemies, and suggested remedies. An extensive bibliography completes the bulletin.

Orange insects and diseases, P. H. ROLFS (*Proc. Florida Hort. Soc.*, 1898, pp. 34-38, figs. 4).—The author describes the principal insect and fungus pests of the orange, and directions are given for combating them.

The quince curculic, M. V. SLINGERLAND (*New York Cornell Sta. Rpt. 1898*, pp. 695-715, figs. 10).—A reprint of Bulletin 118 of the station (E. S. R., 10, p. 565).

A review of entomological work on sugar cane in Java, L. ZEHNTNER (*Meded. Proefstat. Oost Java, n. ser., 40*, pp. 25; abs. in *Zool. Centbl., 5* (1898), No. 23-24, pp. 803, 804).—The animals injurious to sugar cane are enumerated and suggestions given for combating them. The list includes 9 wild animals, 3 birds, 8 Coleoptera, 29 Lepidoptera, 2 Diptera, 22 Rhynechota, 16 Orthoptera, 3 Termites, 7 Physopoda, 3 Aphides, and 3 worms. A number of new species are described.

Leaf miners of sugar cane, L. ZEHNTNER (*Meded. Proefstat. Oost Java, n. ser., 42*, pp. 14, pl. 1; abs. in *Zool. Centbl., 5* (1898), No. 23-24, p. 813).—Studies are given of *Aphanisticus krügeri* and *A. consanguineus*.

Leaf borers of sugar cane in Java, L. ZEHNTNER (*Arch. Java Zoölerind., 1896*, No. 16, pp. 12, pl. 1; abs. in *Zool. Centbl., 5* (1898), No. 23-24, p. 813).—Describes *Hispidella wakkeri*, n. sp.

Some scale insects of sugar cane, L. ZEHNTNER (*Meded. Proefstat. Suikerriet W. Java Bul. 37*, pp. 14, pl. 1).—The author describes the following new species: *Chionaspis madinnensis*, *C. tegalensis*, an unnamed species of *Chionaspis*, and *Physcus flavidus*.

Notes on spraying and on the San José scale, H. P. GOULD (*New York Cornell Sta. Rpt. 1898*, pp. 579-592, figs. 2).—A reprint of Bulletin 144 of the station (E. S. R., 10, p. 468).

Carbolic soap and the green fly, J. H. WALKER (*Gard. Chron., 3. ser., 24* (1898), No. 607, p. 125).—The author states that carbolic soap is one of the most efficient means for the destruction of the common rose aphid, and if properly applied will not only prove efficient for this, but for other species of aphids. The directions for preparation given are to dissolve 1 lb. of carbolic soap in 2 gal. of boiling water, to be kept tightly corked until required. Add 1 pt. of this to 4 pt. of soft water, and it may be applied morning and evening to infested plants.

Report of the entomologist, C. H. FERNALD (*Massachusetts Hatch Sta. Rpt. 1897*, pp. 102-105).—In this brief review of the year the author notes the appearance in several places in the State of the San José scale, the presence in small numbers only of the army worm, and its more or less extensive parasitism by a fly, the abundance of plant lice during the year, the occurrence of the tobacco cutworm (*Carneades messoria*) in the Connecticut Valley, and of the cankerworm. Relative to the latter different remedial measures are briefly discussed. The more effectual and cheaper method (compared with painting tree trunks with Morrill's tree ink) is thought to be spraying with Paris green in the usual proportions of 1 lb. to 150 gal. water.

Orchard pests, V. P. HEDRICK (*Utah Sta. Bul. 55*, pp. 157-168, pls. 6, figs. 2).—The author gives brief descriptions and suggests methods of treatment for the following insect and fungus pests: Codling moth, clover mite or red spider (*Bryobia pratensis*), pear slug, woolly aphid, peach-tree borer, aphides or plant lice, pear-leaf blister, San José scale, leaf-blight or shot-hole fungus, black knot, crown gall, mildew of the grape, and gooseberry mildew.

Formulas are given for the preparation of fungicides and insecticides and directions given for their application.

Some spraying mixtures, G. W. CAVANAUGH (*New York Cornell Sta. Rpt. 1898*, pp. 719-721).—A reprint of Bulletin 149 of the station (E. S. R., 10, p. 568).

Important insecticides: Directions for their preparation and use, C. L. MARRATT (*U. S. Dept. Agr., Farmers' Bul. 19*, p. 31, figs. 3).—This is the fourth revised edition of this bulletin (E. S. R., 6, p. 315).

A successful lantern trap, C. P. GILLETTE (*Proc. Soc. Prom. Agr. Sci., 1897*, pp. 69, 70, fig. 1).—A lantern trap for insects is described and figured, and directions for using it are given.

Lepidoptera at light and sugar, C. P. GILLETTE (*Proc. Soc. Prom. Agr. Sci., 1897*, pp. 64-68).—Records of moths taken at light and at sugar have been kept each year since 1890. Some of the data are presented in tabular form.

"A little computation upon the figures in the table will show that only 44 + per cent of all the moths taken were males and 55 + per cent were females. Of these females, 87 per cent still possessed eggs in their ovaries. Or, to put it differently, 49 per cent of all moths taken were gravid females. . . . So far as my studies have gone, I have no reason to think there is any family of moths, or any considerable number of species that fly to light in which a good proportion of gravid females are not found. I have come upon a few species, however, that have given very few gravid females at either light or sugar and most notable among these are 3 species of *Chorizagrotis*, viz, *Auxilaris*, *Introferens*, and *Agrestis*. . . . It is almost always the case that the males of a species are taken for a few nights before the females appear and continue longer, but if frequent captures are made during the continuance of the brood, the two sexes are usually taken in about even numbers. . . . It is fair to conclude that whenever moths are coming freely to lights or sugar, especially the former, a good proportion are females that have not deposited their eggs, and among those that so come, are several of our most destructive night-flying species."

The new law providing for the suppression and control of insect pests and plant diseases in Maryland, W. G. JOHNSON (*Maryland Sta. Bul.* 55, pp. 147-149).—This article gives the text of a recent law for the suppression and control of insect pests and plant diseases in Maryland and discusses it briefly.

Cordyceps militaris on a beetle, W. F. JOHNSON (*Irish Nat.*, 8 (1899), No. 1, p. 24).—Notes the occurrence of this fungus on *Necrophorus ruspator*.

FOODS—ANIMAL PRODUCTION.

The nutritive value of beef when cooked in the usual ways, K. FÖRSTER (*Der Nährwerth des Rindfleisches bei den gebräuchlichen Zubereitungsarten. Inaug. Diss., Berlin, 1897; abs. in Chem. Centbl., 1898, I, No. 21, pp. 1145, 1116; and Ztschr. Untersuch. Nahr. u. Genussmth., 1898, No. 2, p. 782*).—The investigations were summarized as follows: Lean beef contains on an average 75.15 per cent water, 13.11 per cent protein, 7.65 per cent fat, and 4.31 per cent ash. When prepared for the table by the usual methods there was no loss of protein. Meat from the hind quarter contains 4.85 to 12.3 per cent fat, that from the shoulder 3.57 to 16.55 per cent. In the digestion experiments reported it was shown that white wine exercised a favorable influence on the digestibility of meat. The feces from a meat diet contained on an average 6.82 per cent protein, 10.39 per cent fat, and 14.33 per cent ash. When an abundant meat diet was consumed indican appeared in the urine as well as an increased amount of uric acid and nitrogen. When small amounts of meat were consumed at frequent intervals it was better digested than when larger amounts were consumed at less frequent intervals. In general beef was well digested. The coefficients of digestibility were: Dry matter, 93.08; nitrogen, 97.26; fat, 85.5; and ash 83.1 per cent. The meat from the shoulder was from 1 to 2 per cent more thoroughly digested than that from the hind quarter. The effect which preparation had on the beef is shown by the following list, the materials being arranged in the order of digestibility: Smoked beef, roast beef, beef boiled in water (boiling at the start), raw beef, corned beef, broiled beef, and beef boiled in water cold at the start.

The influence of sugar on the power of muscles to produce work, SCHUMBURG (*Ztschr. Ver. Rübenc. Ind., 1898, pt. 2, No. 505, pp. 110-129, pl. 1, figs. 10*).—A number of experiments with man briefly noted in a previous publication (*E. S. R., 9, p. 175*) are reported in detail. In some periods of the experiments the subject was given a solution of 30 gm. of sugar in 200 cc. of water; in other periods a solution of 0.25 gm. of dulcin in the same quantity of water. The two solutions had the same degree of sweetness. The amount of muscular work performed by the subject under the influence of these solutions and under normal conditions was compared. The work, which consisted in lifting a weight with the finger, was measured by a Mosso ergograph. The subject did not know the purpose of the experiments or the difference in the character of the two solutions.

The conclusion was reached that sugar even in such small amounts as 30 gm. enables the muscles to perform an extraordinary amount of work.

The author calls attention to the fact that practical tests of the value of sugar as a source of muscular energy are necessary.

Studies of dietaries, W. O. ATWATER and A. P. BRYANT (*Connecticut Storrs Sta. Rpt. 1897, pp. 130-153*).—In continuation of the work of previous years (*E. S. R., 8, p. 419; 9, pp. 779, 780*) a number of dietary studies are reported. The results are briefly summarized in the following table:

Results of dietary studies—food eaten per person daily.

	Cost.	Protein.	Fat.	Carbohy- drates.	Fuel value.
	<i>Cents.</i>	<i>Grams.</i>	<i>Grams.</i>	<i>Grams.</i>	<i>Calories.</i>
Man in Adirondack Mountains in winter		186	150	386	3,750
Man in Adirondack Mountains in spring		130	119	284	2,805
Farmer's family in New York		90	204	489	4,270
Man in Adirondack Mountains in summer	17.3	85	107	229	2,280
Two women in the Adirondacks in summer	20.8	101	139	291	2,900
Private boarding house in Middletown, Conn.		95	130	358	3,065

Experiments on the digestion of food by man, W. O. ATWATER and F. G. BENEDICT (*Connecticut Storrs Sta. Rpt. 1897, pp. 151-167*).—A number of experiments on the digestibility of mixed diet are reported. In some cases the subjects were at rest, in others work was performed. In several tests alcohol formed a part of the day's ration. These digestion experiments were made in connection with metabolism experiments with subjects in the respiration calorimeter, Nos. 39, 40, 45, and 46 being in connection with those reported on p. 664. Each of the two periods covered 4 days, the subject being in the respiration chamber during the second period but not during the first. Full analyses were made of the food and feces. The fuel value was determined with a bomb calorimeter. In calculating the energy available suitable allowance was made for the fuel value of urea. In the following table is shown the coeffi-

icients of digestibility and the energy available in the different experiments.

Result of digestion experiments with man.

Number of experiment.	Metabolism experiment number.	Description.	Protein.	Fat.	Carbo- hydrates.	Available energy.

A respiration calorimeter and experiments on the conservation of energy in the human body, W. O. ATWATER and E. B. ROSA (*Connecticut Storrs Sta. Rpt. 1897, pp. 212-212, figs. 3*).—The portion of this apparatus which is concerned in the determination of income and outgo of material has already been described (*E. S. R., 9, p. 863*). In the present publication the portion which has to do with the measurement of income and outgo of energy is described, as well as check experiments in which heat was liberated in the respiration chamber by burning alcohol and by means of an electric current and 2 experiments with man. The metal walls of the respiration chamber are kept at the same temperature, therefore no heat can pass in or out of the chamber through the walls. The ventilating current is kept at the same temperature as it enters and leaves the chamber. Heat generated in the chamber is absorbed by a current of water, which passes through “absorbers” within the chamber. The various devices for measuring the current of air, controlling its temperature, for sampling the air, measuring the heat of the incoming and outgoing currents of water, and other devices are described in detail.

“In order that the ventilating current of air shall not carry out of the chamber any more or any less heat than it brings in, the temperature must be the same when it enters as when it leaves. Accordingly the incoming air, which leaves the brine tank [where it is largely freed from moisture by cooling] at a very low temperature, is warmed before its entrance to the chamber to the temperature of the outgoing

air. The devices for this purpose are such that the difference of temperature of the incoming and outgoing currents can be kept inside of 0.01° C. In actual experiments the positive and negative differences are made to counterbalance each other."

The arrangements for preventing the passage of heat through the walls of the calorimeter are described as follows:

"The difference between the temperature of the copper wall and that of the zinc is measured by a system of thermo-electric junctions, in 304 pairs, distributed over the sides, top and bottom, one-half of the junctions (iron-German silver) being in close thermal contact with the copper wall and the other half (German silver-iron) with the zinc wall. The difference of temperature of the two walls is made as small as possible by warming or cooling the air in the space B, and the positive and negative differences are made to counterbalance each other. Thus the corresponding movements of small quantities of heat inward and outward also counterbalance, and the chamber neither gains nor loses heat through the walls.

"For the measurement of differences of temperature, as well as for the warming and cooling, the walls of the calorimeter are considered as divided into four sections, viz, (1) the top; (2) the upper half of the sides or 'upper zone;' (3) the lower half of the sides or 'lower zone;' (4) the bottom. The systems of thermo-electric elements for heat measurements, of wires for warming and of water pipes for cooling, are each divided into corresponding sections."

The heat carried out by the water current is measured as follows:

"The principle employed is simple. The chamber neither gains nor loses heat by the air current nor through the walls. The current of cold water which passes through the heat absorbers inside the chamber is caused to enter at a temperature generally but little above the freezing point, and to flow out at such a rate as to absorb and carry off the heat just as fast as it is generated inside the apparatus. The temperature of the water is measured as it enters and as it comes out. An electrical thermometer indicates the difference of temperature between the incoming and outgoing water currents by the difference of resistance of two coils of thin copper wire, of which one is in each pipe at the place of entrance or exit from the calorimeter. The difference is measured by a Wheatstone bridge on the observer's table. The mass of water is measured automatically by apparatus at the right of the window of the respiration chamber.

"From the mass of the water which has passed through the absorber in a given time and the rise in temperature the quantities of heat brought out are readily calculated. To this is to be added a certain amount of heat which is carried away with the water vapor produced in the apparatus. This is practically the difference between the water vapor in the incoming and outgoing air. From the amount of this vapor, and its latent heat at the temperature of exit, the amount of heat it carries out is easily computed."

The apparatus for measuring and sampling the ventilating current is described as follows:

"Three forms of apparatus have been used for maintaining the air current and measuring its volume. One consisted of an ordinary air pump with a meter made by Elster in Berlin. With this we have been unable to make measurements as accurate as seem to us desirable.

"For taking samples of air for analysis aspirators of 150 liters capacity were employed at the outset and are still used. The measurements with these have been found quite accurate. The most satisfactory arrangement we have found, and one which serves the threefold purpose of maintaining the air current, measuring its

volume, and delivering aliquot samples of convenient size for analysis, is an apparatus designed and made by Mr. O. S. Blakeslee, and appropriately designated by him as a "meter pump." The essential parts for maintaining the air current and measuring its volume are cylinders of steel. There are two pumps which work in unison. Three steel cylinders are employed for each pump. The inner and outer cylinders are arranged concentrically, with an annular space 1.2 cm. in width between them. This space is partly filled with mercury. Between the inner and outer cylinders, which are stationary, plays a central cylinder, its lower portion being immersed in the mercury. The central cylinder is closed at the top and is raised and lowered by a walking beam. The inner cylinder is also covered at the top, but through this cover are two circular apertures opened and closed alternately by an automatic valve, actuated by a compressed-air mechanism underneath. Connected with these apertures are pipes passing downward through the inner cylinder. One serves to convey the air, as it comes from the chamber, into the pump as the central cylinder rises. As the cylinder falls the other pipe conveys the air outward, and thus plays the part of a discharge pipe. The automatic valves open and close the inlets and discharge pipes so that with each stroke of the inner cylinder the air is cut off at the proper time. The length of the stroke of the cylinder is determined exactly by rods provided with stops, these rods playing through guides on two sides of each cylinder, and by this arrangement the only variation is that which comes with the very slight changes in the length of the rods due to changes of temperature. The air coming from the discharge pipe escapes into the room, but by a special device the air of each fiftieth stroke of each pump is diverted into a receptacle, from which it is being constantly drawn for analysis."

In the electrical check experiment a total of 3,017.4 calories of heat was liberated in the chamber. The amount measured was 3,016.7 calories. In other words, the two values were practically identical.

"In the alcohol tests the average amounts found by actual experiment were, for carbon, 99.6 per cent, hydrogen, 100.6 per cent, and heat, 99.8 per cent of the theoretical amounts. It thus appears that this apparatus, when used for the analysis of alcohol and the determination of its heat of combustion, gives results nearly, if not quite, as accurate as are obtained by the ordinary laboratory methods."

Of the two experiments with man, one was made in May, 1897, and the other in January, 1898. The former is reported in much more detail than the other.

"The experiments with a man each continued during 8 days, during the last 4 days and 5 nights of which the subject was in the respiration chamber. The diet during each experiment was uniform through the whole 8 days. The purpose of the preliminary period of 4 days was to bring the body into at least approximate nitrogen and carbon equilibrium with the food and to make the determination of the amounts of nutrients absorbed as nearly accurate as practicable. The income and outgo of nitrogen were determined during this period, which thus amounted to a digestion and metabolism experiment. The metabolism of nitrogen, carbon, hydrogen, and energy was determined during the final period of 4 days.

"In one of the 2 experiments the man had as little muscular exercise as he could well have with comfort. In the other he was engaged in quite active muscular exercise. The external muscular work was expended in driving a dynamo which produced an electric current. The latter was passed through a resistance coil, and the energy was transformed into heat, which was measured with that given off from the body."

The daily income and outgo of nitrogen and carbon and the calculated loss of protein and fat is shown in the following table.

Average daily income and outgo of nitrogen and carbon, with the estimated gain or loss of protein and of fat.

Number of ex- periment.	Subject and occupation.	Nitrogen.				Carbon.				Calculated gain or loss.		
		In food.	In feces.	In urine.	Gain () or loss (-).	In food.	In feces.	In urine.	In re- spira- tory prod- ucts.	Gain () or loss (-).	Of pro- tein.	Of fat.
		Gms.	Gms.	Gms.	Gms.	Gms.	Gms.	Gms.	Gms.	Gms.	Gms.	Gms.
6	E. O. at work ..	19.1	1.5	16.5	1.1	334.0	12.4	12.5	345.2	-36.1	-6.9	-51.9
9	E. O. at rest....	19.1	1.3	18.4	-1.6	254.7	12.9	12.6	223.6	5.6	-3.6	9.8

In the following table is shown the daily income and outgo of protein and energy in the same experiments:

Comparison of daily income and outgo of protein and energy.

Number of experi- ment.	Subject and occupation.	Protein.		Energy.			
		Of food.	Actually oxidized.	Of food.	Of material actually oxidized.	Measured by respi- ration calori- meter.	Difference between theoretical and meas- ured.
		Gms.	Gms.	Calories.	Calories.	Calories.	Per cent.
6	E. O. at work.....	119.4	103.1	3,678	3,864	3,739	3.2
9	E. O. at rest.....	119.4	115.0	2,717	2,334	2,329	1.1

These experiments and their bearing upon the problem of the conservation of energy in the animal body are discussed in some detail.

“The differences between the income and outgo of energy as measured in these two cases were 3.2 and 1.1 per cent, and averaged 2.2 per cent. The amount of energy as measured was in each case less than the theoretical amount of potential energy in the material consumed. The larger discrepancy was in the first experiment. Certain sources of error in this appear to have been eliminated, at least in part, in later experiments, of which the second was one. In these latter the agreement is very close, the energy found being about 39 per cent of the theoretical. On the whole the agreement between theoretical amounts of energy transformed and those found in the experiments is as close as could be expected under the circumstances.

“It would be wrong to assume that these experiments demonstrate completely the conservation of energy in the animal organism. They do, however, approach very closely to such demonstration for the case of the man under experiment.”

Digestion experiments,¹ F. E. EMERY and B. W. KILGORE (*North Carolina Sta. Bul. 118, pp. 275-299*).—In previous work of the station (E. S. R., 3, p. 452; 4, p. 736; 5, p. 1081; 7, p. 702) it was found that when cotton-seed meal was fed with coarse fodders there was an increase in the total amount of carbohydrates digested more than sufficient to make up for the loss observed in the percentage of protein digested. A number of experiments were therefore made with 4 sheep to determine the digestibility of timothy and crab-grass hay fed alone and with

¹ A bulletin bearing the same number and date, in which the detailed tables of the digestion experiments were omitted, was also issued by the station.

different amounts of cotton-seed meal. The sheep were kept in suitable stalls and were fed corn silage morning and noon and with mixed hay at night for a few days before the tests proper began. The experiments were conducted by the usual methods. The weights of the sheep were recorded in every case. When cotton-seed meal was fed with the timothy hay or crab-grass hay, the digestibility of the hay alone was computed by taking into account the coefficients of digestibility of the cotton-seed meal as determined in previous experiments. The coefficients of digestibility of the different rations is shown in the following table:

a Only for sheep No. 2.

An experiment was also attempted with timothy hay and undecorticated sunflower-seed meal, but the sheep would not eat the meal. The authors believe that the meal may have been too old.

Investigations on the amount of food and energy required for fattening full-grown steers, O. KELLNER, A. KÖHLER, ET AL. (*Landw. Vers. Stat.*, 50 (1898), No. 3-1, pp. 215-296).—In continuation of previous work (E. S. R., 9, 167), the authors report experiments with 3 steers to determine the amount of food and energy required for fattening. The methods followed are similar to those previously reported, and the same respiration apparatus was used. In the first test steer 1, weighing about 750 kg., was fed a ration consisting entirely of meadow hay, 9 kg. In the second test steer 2, weighing about 750 kg., was fed a ration of 6 kg. meadow hay and 3 kg. of rye bran. In the third experiment steer 3, weighing about 860 kg., was fed a ration of 6 kg. meadow hay, 5 kg. of beet chips, and 1 kg. of rye bran. The coefficients of digestibility in the 3 experiments are as follows:

Coefficients of digestibility.

	Dry matter.	Organic matter.	Crude protein.	Protein.	Non-albuminoid nitrogen.	Fat.	Nitrogen-free extract.	Crude fiber.
	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>
Experiment 1, steer 1: Meadow hay.....	57	59	50	57.3	100	43.8	61.8	53.2
Experiment 2, steer 2: Meadow hay, rye bran.....	84.5	86.5	83.9	94.8	100	83.7	89.5	59.0
Experiment 3, steer 3: Meadow hay, beet chips, and rye bran....	68.4	70.6	59.2	67.5	100	31.6	76.2	65.4

The income and outgo of nitrogen and carbon was as follows:

Income and outgo of nitrogen and carbon.

	Nitrogen.				Carbon.				
	In food.	In urine.	In feces.	Gain (+) or loss(-).	In food.	In urine.	In feces.	In respiratory products.	Gain (+) or loss(-).
	<i>Grams.</i>	<i>Grams.</i>	<i>Grams.</i>	<i>Grams.</i>	<i>Grams.</i>	<i>Grams.</i>	<i>Grams.</i>	<i>Grams.</i>	<i>Grams.</i>
Experiment 1, steer 1, 730.4 kg. hay, 27.65 kg. water.	109.40	65.57	57.66	-13.83	3,403.7	183.5	1,506.1	1,057.3	-343.2
Experiment 2, steer 2, 5.197 kg. hay, 2.621 kg. rye bran, 23.96 kg. water....	164.24	111.44	55.61	- 2.81	3,651.6	187.8	1,256.9	2,233.9	- 27.0
Experiment 3, steer 3, 5.179 kg. hay, 4.328 kg. beet chips, 0.866 kg. rye bran, 34.81 kg. water.....	179.82	96.10	78.67	+ 5.05	4,695.2	184	1,511.5	2,892.8	+106.9

From the balance of nitrogen and carbon, it was calculated that steer 1 lost 84.5 gm. of water-free flesh, 391.2 gm. fat; steer 2 lost 17.2 gm. water-free flesh and 23.7 gm. fat; or, in other words, there was practically a nitrogen equilibrium. Steer 3 gained 30.9 gm. water-free flesh and 118.8 gm. fat. The authors calculated that an adult steer, when in good condition for fattening, requires per day, per 1,000 kg. live weight,

0.85 kg. digestible crude protein (equal to 0.78 true protein) and 6.64 kg. nitrogen-free material. Of these quantities a small amount of protein (13 gm.) and of nitrogen-free material (equal to 106 gm. fat) was required for the building and repair of hair, of hoof, skin, etc.

Following methods outlined in the earlier investigations, the income and outgo of energy in the 3 experiments was calculated.

Income and outgo of energy.

	Income.	Outgo.
	<i>Calories.</i>	<i>Calories.</i>
Experiment 1:		
Meadow hay (7,303 gm.)	32,252.2	
Feces (4,668.2 gm.)		14,653.5
Nitrogen evolved in drying feces		15.5
Urine		1,789.9
Methan (156.8 gm.)		2,077.0
Protein tissue lost (84.5 gm.)	374.5	
Fat tissue lost (391.2 gm.)	3,716.4	
Total outgo		18,535.9
Balance	17,807.2	
Experiment 2:		
Meadow hay (5,197 gm.)	22,951.5	
Rye bran (2,621 gm.)	12,158.3	
Feces (2,641 gm.)		12,331.1
Nitrogen evolved in drying feces		14.7
Urine		1,918.6
Methan (165.4 gm.)		2,190.9
Protein tissue lost from body (17.2 gm.)	76.2	
Fat tissue lost (23.7 gm.)	225.1	
Total outgo		16,455.3
Balance	18,654.5	
Experiment 3:		
Meadow hay (5,179 gm.)	22,787.6	
Beet chips (43.28 gm.)	17,855.2	
Rye bran (866 gm.)	4,033.5	
Feces (3,278 gm.)		14,733.6
Nitrogen evolved in drying feces		27.4
Urine		1,820.9
Methan (267.09 gm.)		3,536.7
Protein tissue gained (30.9 gm.)		317.5
Fat tissue gained (118.8 gm.)		2,052.0
Total outgo		20,118.6
Balance	24,557.7	

As shown by the 3 experiments the average energy required of a steer per 1,000 kg. live weight is 24,979 calories, when the temperature of the surrounding air is 15.7° C. The deduction is drawn from the experiments that feeding is less profitable the longer the feeding period is prolonged. The authors discuss the energy of the feces, urine, and methane excreted, and deducting these factors from the energy of the food, calculate its physiological nutritive effect. The physiological nutritive effect per gram of meadow hay in the first experiment was calculated to be 3.435 calories; of 1 gm. of meadow hay and rye bran in experiment 2, 3.722, and of 1 gm. of meadow hay, beet chips, and rye bran in experiment 3, 3.593 calories. The physiological nutritive effect of 1 gm. of digestible rye bran is calculated to be 4.102 calories. The experimental data are reported in full in tabular form.

Fattening cattle in North Dakota. J. H. SIEPPERD (*North Dakota Sta. Bul. 33, pp. 281-292*).—The author discusses at some length cattle feeding under existing conditions in North Dakota. Investigations made in different parts of the country bearing upon the subject are quoted. In his opinion cattle can be profitably fattened on corn fodder, hay, and barley on nearly all the farms of North Dakota. A test of the comparative value of bran and bran and shorts for fattening steers is reported. The test was made with 2 lots of 5 grade steers each. These animals were believed to be on an average better than the range stock of the State. The experiment proper was preceded by a preliminary period of 1 month. All the steers were fed bran and shorts 1:1 and 1 lb. of linseed meal per head daily. The steers in lot 1 ate an average of 12 lbs. of grain per head daily and gained a little less than $1\frac{1}{2}$ lbs. per head. Lot 2 ate practically the same amount of grain and gained a little more than $1\frac{1}{3}$ lbs. per head daily. The test proper began immediately after the close of the preliminary period and continued 12 weeks. Lot 1 was fed barley and lot 2 bran and shorts 1:2. Each lot was fed oil meal in the proportion of 1 lb. to 10 lbs. of grain. Lot 1 ate on an average 16 lbs. of grain daily and lot 2, $14\frac{1}{3}$ lbs. The steers were confined in stalls and were fed separately and given all the hay they would eat in addition to the grain. The financial statement is based on barley at 75 cts., linseed meal at \$1, bran and shorts at 60 cts. per 100 lbs., and hay at \$4 per ton.

The results of the test are shown in the following table:

Result from feeding steers barley and bran and shorts.

Kind of feed.	Average weight of steers at beginning of test.	Grain eaten per day.	Hay eaten per day.	Gain in weight per day.	Grain eaten per lb. gain.	Profit per steer.
	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>	
Lot 1, fed barley	1,080.4	15.9	16.9	1.74	9.14	\$4.51
Lot 2, fed bran and shorts	1,054.8	14.32	17.16	1.35	10.6	5.03

The principal conclusions follow:

“Range steers require a long preliminary feeding before a heavy supply of grain is given them.

“Eleven hundred and fifty pound steers fed for a period of 6 months will eat an average of about $16\frac{1}{2}$ lbs. of grain and 12 lbs. of hay per day.

“Range steers fed in a commercial way will gain from $1\frac{1}{3}$ lbs. to $1\frac{1}{2}$ lbs. per day.

“Cattle should neither be gorged nor starved for feed or water before shipment is made. A medium quantity of dry feed is best.

“Barley gives a heavier gain per 100 lbs. of grain fed and a higher rate of gain per day than does bran and shorts.

“With the prices for feed which prevailed locally, bran and shorts gave the cheaper gain and the greater profit.”

Fattening steers in winter. T. SHAW (*Minnesota Sta. Bul. 58, pp. 469-509, figs. 2*).—These tests were made in continuation of work previously reported (E. S. R., 8, p. 241).

Fattening Minnesota steers (pp. 469-485).—In order to study the relative value of light, moderate, and heavy feeding and the relative merits of steers of different grade a test was made with 3 lots, each containing a Shorthorn, a Hereford, and an Aberdeen Poll steer. They were about 2 years old and were from cows of a common mixed breed and a pure-bred sire. They were all purchased in Minnesota. The net cost of the Aberdeen Poll steers was \$3.35 per 100 lbs.; the Shorthorns \$3.67, and of the Herefords \$3.70. The test began January 6, 1896, and covered 150 days. At the beginning of the test lot 1 was fed per head daily 5 lbs. of meal composed of equal parts of bran, oats, barley, and corn; lot 2, 7 lbs., and lot 3, 9 lbs. of the same mixture. This was increased 1 lb. per head every 4 weeks. February 10 the animals were given a pound of linseed cake per head daily in addition. On March 16 the amount was doubled and the grain ration was changed to bran, barley, and corn 1:1:2. The maximum amounts of meal fed were 10, 12, and 14 lbs. in the 3 lots, respectively. The steers were fed daily 25 lbs. of corn silage per head in addition to the grain and all the native hay they would eat up clean. They were fed in stalls and were given water twice a day, with salt 2 or 3 times a week. The Herefords were dehorned at the beginning of the test. This interfered with their feeding for about 14 days. The financial statement is based on bran at \$6.50, oil cake \$14 per ton, native hay at \$3, and corn silage at \$1 per ton, and oats at 14 cts., barley 16 cts., and corn 18 cts. per bushel. At the close of the test the steers were sold in St. Paul for \$4.10 per 100 lbs., a shrinkage of 4 per cent being allowed.

The results of the test are shown in the following table:

Summary of results of steer feeding.

	Average amount of food consumed per steer per di. m.			Total weight at beginning.	Total increase per lot.	Average cost of 100 lbs. increase.	Net profit per lot.
	Hay.	Silage.	Meal.				
	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>		
Lot 1.....	6.91	23.04	8.58	3,110	741	\$3.55	\$10.21
Lot 2.....	6.53	21.77	10.48	3,165	776	3.72	9.20
Lot 3.....	5.71	18.07	11.94	3,140	692	4.37	4.70

Fattening range steers (pp. 486-504).—A test similar to the preceding was made with 9 range steers, divided into 3 lots of 3 each. They were purchased in Montana and were worth at the beginning of the test \$3.13 per 100 lbs. In some of the steers Hereford and Polled Aberdeen blood predominated, in others Shorthorn blood. They were a fair type of beef steers. They had been suckled by their dams in winter and when necessary given some hay. Otherwise they fed on the range. The test began December 7, 1896, and closed April 17, 1897. All the lots were fed bran, barley, corn, and linseed cake 3:3:3:1, with hay and silage in addition, lot 1 being fed 7 lbs. of grain per head daily, lot 2 9 lbs., and lot 3 11 lbs. at the beginning of the test. These amounts

were increased 1 lb. per month, until lot 1 was fed 11, lot 2 13, and lot 3 15 lbs. In some instances it was found necessary to diminish the amounts. It was the intention to feed 25 lbs. of corn silage per day, but the amount was finally reduced to 18 lbs. One steer in lot 2 was given no silage. The financial statement is based on barley at 16 cts. and corn 18 cts. per bushel; bran at \$6.50, oil cake at \$14, hay at \$3.50, and corn silage at \$1.25 per ton. The results are given in the following table:

Summary of results of steer feeding.

	Average amount of food consumed per steer per diem.			Total weight at beginning.	Total gain per lot.	Total cost of food consumed per lot.	Average cost of 100 lbs. of gain.	Net profit per lot.
	Hay.	Silage.	Meal.					
	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>			
Lot 1	10.58	18.17	9.08	3,620	709	\$25.71	\$3.94	\$53.20
Lot 2	8.99	20.31	11.17	3,413	785	28.35	3.69	51.21
Lot 3	9.06	17.44	13.09	3,465	758	30.70	4.21	48.34

The following are some of the deductions drawn:

"The wonderfully low cost of the food fed should not be overlooked. The average cost of feeding one steer per day in the 3 experiments was but 8.36 cts. . . .

"The low cost of the increase per 100 lbs. is also noteworthy. With the steers in all the lots it was \$4.62, while the average price for which it was sold was \$4.66 per 100 lbs. During the 3 years of feeding, therefore, the cost of the increase was less than it sold for. In but few countries of the world could this be accomplished with food charged at market values. . . .

"The net profit on each of the steers in lots 1 was \$1.93 more than on each of the steers in lots 3. It was \$1.11 per animal more than the average profit from each of the steers in lots 2 and 3 combined, and in each of the 3 experiments was the profit greatest on the steers fed the light meal ration. It is fair to infer, then, that had the steers in these lots been fed as the steers in lots 1, \$25.38 additional would have been added to the net profit on the 18 steers in lots 2 and 3. And it should also be borne in mind that the dearer relatively the price of grain, the greater will the contrast be between feeding meal or grain in moderate or in large quantities. The increase in the quantities of meal fed did not result in a decrease in the consumption of fodder to the extent expected. . . .

"The average quantity of meal fed per day in securing the largest profit was only 8.23 lbs. To this must be added some corn which the silage contained. The average amount of silage consumed per day throughout the feeding was a little more than 21 lbs. and it contained a moderate amount of corn, but how much can not be stated. In any event, it would not increase the meal fed daily to those steers to very much beyond 10 lbs. The writer can not but conclude, therefore, that in Western-fed lots much grain is oftentimes fed to no purpose, since from 25 to 30 lbs. of shelled corn are frequently fed per day to one cattle beast and to one pig that feeds upon its droppings."

The feeding value of whole cotton seed, crushed cotton seed, and cotton-seed meal and hulls for finishing steers for market, R. L. BENNETT (*Arkansas Sta. Bul. 52, pp. 47-52*).—A test was made with 3 lots of 5 steers, to compare cotton seed and cotton-seed products. Lot 1 was fed cotton-seed meal and hulls in the same proportion as they exist in the seed; lot 2, whole cotton seed, and lot 3 ground cotton seed.

These materials were fed *ad libitum*. In addition each lot was fed cowpea hay. The test covered 90 days. The steers were fed in large box stalls opening into small lots.

The results of the test are shown in the following table:

Results of steer-feeding experiments.

	Total weight at beginning.	Total food consumed.				Cowpea hay.	Average daily gain.
		Cotton-seed meal.	Cotton-seed hulls.	Whole cotton seed.	Ground cotton seed.		
	Pounds.	Pounds.	Pounds.	Pounds.	Pounds.	Pounds.	Pounds.
Lot 1.....	3,800	2,189	2,909	6,252	2
Lot 2.....	3,806	4,609	6,591	1.9
Lot 3.....	3,826	4,630	6,535	1.9

The principal conclusions follow:

"This trial suggests the practice, when meal and hulls sell for more than seed, or when they sell for relatively the same price, of feeding seed during the first part of the feeding period, not exceeding 60 days, and of feeding meal and hulls during the last part of the period.

"The excess of oil in seed over that in meal would seem to be the cause of the diminished appetite of the steers fed seed when the weather was warm and sultry. The diminished appetites suggest that when seed is to be fed without any meal either corn or bran should partly or wholly replace the seed when the weather affects the appetites to any extent during the last part of the feeding.

"Feeding seed as the only concentrated food for fattening should be done only during the cool part of the year."

Corn meal and shorts as food for pigs, C. S. PLUMB and W. B. ANDERSON (*Indiana Sta. Bul.* 71, pp. 55-60).—A test of the comparative value of corn meal and shorts covering 70 days was made with 2 lots of 3 high-grade Chester White sows each. Lot 1 was fed shorts and corn meal and lot 2 corn meal. The pigs were kept in pens about 30 by 15 ft. with a small shelter. The financial statement is based on shorts at 70 cts. and corn meal at 65 cts. per 100 lbs. At the beginning the total weight of lot 1 was 387.5 and lot 2, 385.75 lbs. The average daily gain per head of lot 1 was 1.68 and of lot 2, 1.55 lbs. The pigs in lot 1 consumed on an average 3.41 lbs. corn meal and the same amount of shorts per day; lot 2 consumed 6.72 lbs. of shorts per day. The cost per pound of gain for lot 1 was 0.0274 cts. and of lot 2, 0.028 cts. The sows in the 2 lots were not pregnant nor suckling young and came into heat at regular intervals during the feeding period. The gains, which were recorded each week, varied. In the author's opinion, no variation in gain in weight could be definitely ascribed to the fact that the sows were in heat.

Feeding pumpkins to pigs, H. T. FRENCH (*Oregon Sta. Bul.* 51, pp. 22-25).—The feeding value of pumpkins was tested with 6 Berkshire pigs 8 months old at the beginning of the trial. They had been pastured on a stubble field for 6 weeks previous to the test. The test proper, which was preceded by a preliminary period of 7 days, began

October 30 and covered 56 days, and was divided into 4 periods of 14 days each. The pigs were fed twice a day pumpkins which had been steamed after cutting up and removing the seeds. When thoroughly cooked the pumpkins were mixed with some shorts and a little salt. The financial statement is based on pumpkins at \$2.50 and shorts at \$12 per ton.

During the entire period the pigs made a total gain of 499 lbs., consuming 7,523 lbs. of pumpkins and 924 lbs. of shorts. The average cost per pound of gain was 2.9 cents. "On the whole the results were quite satisfactory when compared with previous work in feeding grain rations alone. The pigs seemed to relish the food and were very contented." The meat produced was regarded as very satisfactory.

Feeding artichokes to pigs, H. T. FRENCH (*Oregon Sta. Bul. 54*, pp. 26-28).—Six Berkshire pigs which had been pastured on a stubble field were fed artichokes with a little grain (chopped wheat and oats 1:1) from October 22 until December 11. The artichokes were grown near the pens and were gathered by the pigs. It is estimated that the artichokes yielded 740 bu. to the acre. The pigs were weighed every 14 days. During the 8 weeks of the test they gained 244 lbs. and consumed 756 lbs. of grain and the artichokes from an eighth of an acre (92.5 bu.); that is, in addition to artichokes 3.1 lbs. of grain was required for a pound of gain. "In other experiments we have found that it takes about 5 lbs. of mixed grain to produce a pound of gain; hence, on this basis, the artichokes consumed would represent 2 lbs. of grain in producing each pound of gain in live weight."

The attempt was made to feed the artichokes without grain, but this was not successful.

Poultry experiments, W. P. BROOKS (*Massachusetts Hatch Sta. Rpt. 1897*, pp. 37-44).—In continuation of work previously reported (E. S. R., 9, p. 376) tests were made with poultry to learn the effect of condition powder and the value of cut bone *vs.* animal meal and of clover rowen *vs.* cabbage for egg production.

Effect of condition powder (pp. 37-41).—The test, which began January 1 and continued to May 2, was made with 1 lot of 19 and 1 lot of 20 Light Brahma hens. Lot 1 was fed a mixed grain ration, with cut clover and fresh cabbage from time to time. Lot 2 was fed the same ration with the addition of condition powder. The nutritive ratio of the first ration was 1 : 5.16 and of the second 1 : 5.14.

The results are briefly summarized as follows:

Results of feeding poultry with and without condition powder.

	Food consumed.	Cost of food per day per fowl.	Number of eggs produced.	Weight per egg.	Cost of food per egg.
	<i>Pounds.</i>	<i>Cent.</i>		<i>Ounces.</i>	<i>Cents.</i>
Lot 1.....	532.0	0.285	532	1.958	1.24
Lot 2 (condition powder)	549.3	.280	540	1.993	1.25

Samples of the eggs were analyzed. Those from the fowls given condition powder were somewhat richer in dry matter, protein, and fat. The eggs were also tested by housekeepers, but definite conclusions were not drawn. The fowls which had received condition powder were reported as dressing rather better than the other lot. In the author's opinion the differences observed in the 2 lots were too small to be considered decisive, but the conclusion seems warranted that the condition powder did not pay for its use.

Cut bone vs. animal meal (pp. 41, 42).—A test, beginning January 1 and continuing until May 2, was made with 2 lots of 20 Plymouth Rock hens. Each lot was fed a mixed ration with clover and cabbage. In addition lot 1 was fed Chicago gluten and cut bone and lot 2 Buffalo gluten and animal meal. The nutritive ratio of the ration of lot 1 was 1: 5.05 and of lot 2, 1: 4.45. The average results are shown in the following table:

Comparison of cut bone and animal meal for poultry.

	Food consumed	Cost of food per day per fowl.	Number of eggs produced.	Weight per egg.	Cost of food per egg.
	<i>Pounds.</i>	<i>Cent.</i>		<i>Ounces.</i>	<i>Cents.</i>
Lot 1 (cut bone).....	525.5	0.28	508	2.0034	1.3
Lot 2 (animal meal).....	513.1	.25	639	2.0270	.97

As shown by analysis, the eggs from the hens fed cut bone contained rather more protein but less fat than the others. Tests of the cooking qualities of the eggs were not decisive. The author notes that in this trial the animal meal gave better returns than the cut bone as regards egg production, the results being the opposite of those obtained in the experiments of the preceding year.

Clover rowen vs. cabbage (pp. 42-44).—A test of the same duration as the last was made with 2 lots of 19 Plymouth Rock pullets. Both lots were fed wheat, oats, bran, middlings, animal meal, cut bone, and oatmeal. In addition lot 1 was fed clover and lot 2 cabbage. The nutritive ratios of the 2 rations were for lot 1, 1: 4.99 and for lot 2, 1: 4.838. The results are summarized in the following table:

Comparison of clover rowen and cabbage for poultry.

	Food consumed	Cost of food per day per fowl.	Number of eggs produced.	Weight per egg.	Cost of food per egg.
	<i>Pounds.</i>	<i>Cent.</i>		<i>Ounces.</i>	<i>Cents.</i>
Lot 1 (clover rowen).....	519.5	0.29	466	2.0472	1.5
Lot 2 (cabbage).....	559.5	.28	588	1.9880	1.18

Analysis showed that the eggs from the lot fed cabbage contained a higher percentage of dry matter, protein, and fat. As regards weight and cost per egg the trial also showed the superiority of cabbage, but

the flavor and cooking qualities of the eggs from the lot fed clover were regarded as superior.

Skim milk as food for young growing chickens, W. B. ANDERSON (*Indiana Sta. Bul.* 71, pp. 60-63).—A test of the value of skim milk for chickens was made with 2 lots containing 10 Plymouth Rocks and 10 Houdans. Each lot was given all they would eat of a mixture of crushed corn, bran, and ground oats, 2:1:1. Both lots were also fed cracked bone, cabbage, and lettuce and had access to water. The amount of these articles consumed is not recorded. The two lots received the same treatment in every respect, except that lot 2 was given all the skim milk they would eat in addition to the grain ration. The test began July 11 and closed September 5. During the test one chicken in lot 1 died. Lot 1 consumed 179.8 lbs. grain, and the average weekly gain per chicken was 2.62 oz. Lot 2 consumed 217.3 lbs. grain and 90.4 lbs. skim milk, and the weekly average gain per chicken was 4.46 oz. The following conclusions were drawn:

“If skim milk be added to the ration fed to young chickens it will increase the consumption of the other foods given. The great increase in average gain was coincident with the periods when the greatest amount of skim milk was consumed. Skim milk is especially valuable as a food for young chickens during the hot, dry weather, and becomes of less importance as the chickens grow older and the weather becomes cooler.”

Gravel and sand in the digestive apparatus of fowls, I. ABOZIN (*Selsk. Khoz. i Lyevor.*, 187 (1897), No. 12, pp. 595-604).—Several experiments were made with hens to determine whether the gravel and sand eaten have any other function besides assisting in grinding the food. In the first test 2 sitting hens were fed buckwheat mush and sour milk but no sand or gravel. After 10 days one of the hens was killed. She had lost 202 gm. in weight. Not more than a gram of sand and gravel was found in the digestive tract, and no sand was found in the feces. The second hen was killed at the end of 20 days and dissected. She had lost 163 gm. in weight. The stomach contained 10 gm. of gravel but none was found in the feces. In both cases the bones were thin and brittle. The skeleton formed only 5 per cent of the total live weight, instead of 6 per cent, which is normal.

The test was repeated several times. In some cases the hens were fed soft foods, in other cases grain; they were given no sand or gravel. In every case the bones became thinner, more crumbly, and weighed less than normal.

The principal conclusions reached were the following: Gravel and sand are uniformly distributed throughout the food in the stomachs of fowls. This material renders the stomach contents porous and thus makes digestion more regular and also renders the passage of the food from the stomach into the intestine more rapid and easy. Gravel and sand are in large part if not entirely dissolved in the stomach of fowls and furnish nutritive material for the bones. The author discusses

at some length the conclusions of Kalugin (E. S. R., 8, p. 718).—
P. FIREMAN.

Some practical applications of results of food investigations, W. O. ATWATER and A. P. BRYANT (*Connecticut Storrs Sta. Rpt. 1897*, pp. 168-188).—The practical value of food investigations is discussed and a table is given in which foods are divided into a number of groups. The different members of each group furnish nearly the same amounts of protein and energy. It is believed that such tables will prove useful in devising menus. A number of sample menus for a family equivalent to 4 persons at moderate muscular work are also given.

Fish as food, C. F. LANGWORTHY (*U. S. Dept. Agr., Farmers' Bul. 85*, pp. 30).—Statistics are given showing the importance of the fishery industry in the United States; the composition, nutritive value, and digestibility of fish are discussed, as well as its place in the diet. Sample menus are given showing that the proper amount of protein and energy may be readily furnished by a diet containing a considerable amount of fish. Some of the possible dangers from eating fish which has not been handled in a cleanly manner, or which is not properly preserved, are pointed out.

Soft clams as human food, E. CUTTER (*Dietet. and Hyg. Gaz.*, 15 (1899), No. 1, pp. 55, 56).—The author believes that soft clams (*Mya arcuaria*) have a high food value.

The measurement of muscular energy in man, L. HERMANN (*Arch. Physiol. [Pflüger]*, 23 (1898), No. 10, pp. 429-437).—The article is based on experiments by C. Hein and T. Siebert.

The diet of laborers on the docks, P. IVANOFF (*Vestnik Obsh. Hig. Subed. i Prakt. Med.*, 31 (1896) No. 1, Pt. VIII, pp. 4-7; *abs. in Rev. Hyg.*, 19 (1897), p. 753).—An extended study is reported of the dietary of the laborers at the Cronstadt docks. In general it was found that they consumed from 216 to 220 gm. protein, 95 gm. fat, and 931 gm. carbohydrates, the total cost being about 13 cts. per day. During the Lenten season and other Church fasts, the amount of fat was diminished to 45 gm. per day and the carbohydrates increased to 1,040 gm. Deducting the amount of indigestible matter, the dietary was thought to furnish about the amount required by Voit's standard.

Improved forms of bomb calorimeter and accessory apparatus, W. O. ATWATER and O. S. BLAKESLEE (*Connecticut Storrs Sta. Rpt. 1897*, pp. 199-211, figs. 8).—A detailed description is given of an improved form of the bomb calorimeter described in Bulletin 21 of this office (E. S. R., 7, p. 148).

Analyses of foods, feeding stuffs, and other products, W. O. ATWATER and F. G. BENEDICT (*Connecticut Storrs Sta. Rpt. 1897*, pp. 189-198).—Analyses are reported of corn stover, oat straw, hay from mixed grasses, hay of second quality, meadow hay, oat hay, corn silage, Buffalo gluten feed, Chicago gluten meal, Rockford gluten feed, corn meal, corn and cob meal, ground oats, fine wheat feed, linseed-oil meal, rye meal, wheat bran and potatoes, and also of the food materials and feces examined in connection with the digestion and metabolism experiments with man reported elsewhere (p. 663).

Feeding of animals and the composition of a number of feeding grains, hays, and other feeding stuffs, P. BONAUME (*Rap. An. Sta. Agron. [Mauritius]*, 1897, pp. 57-91).—The author discusses the feeding of animals in general and reports the composition of a large number of feeding stuffs grown in Mauritius. Among others these include: Seeds and grains—*Mucuna atropurpurea*, *Dolichos lablab*, *Phaseolus inamonus*, *Dolichos biflorus*, *Leucaena glauca* (whole and ground), *Cajanus*, lentils, barley, oats, maize, flaxseed, and rice. Roots, fruits, etc.—Manioc, manioc flour, cassava, arrowroot, carrots, and sugar-cane sprouts. The forage plants include: Dried sugar-cane leaves, sugar-cane sprouts, hay from a number of leguminous plants, and hay of mixed grasses. The green forage plants include: Saltbush, aloe stalks, tops and blossoms of maize, cowpeas, banana stalks, and the leaves of *Leucaena glauca*, *Media azderach*, *Accacia lebbeck*, *Terantheria laurifolia*, *Artocarpus integrifolia*, and *Telferia*. An analysis of the ash of manioc is also given.

Experiments on the fermentative action of the liquid in the small intestine, F. KRÜGER (*Ztschr. Biol.*, 37 (1898), No. 2, pp. 229-260).—The principal conclusions follow: The ferment of the mucous membrane of the small intestine did not cause cleavage of protein or fat. It saccharified cooked starch, but did not invert cane sugar.

Concerning the origin of domestic cattle, A. DAVID (*Landw. Jahrb. Schweiz*, 11 (1897), pp. 117-152, pls. 12).—This article is based on studies of the fragments of bone found in the lake-dwelling remains of the Bielerssee.

Crosses between the zebra and the horse, F. STEINRIEDE (*Deut. Landw. Presse*, 25 (1898), No. 83, pp. 885, 887, figs. 2).—References are given to a number of such crosses.

Advantages and disadvantages of modern methods of poultry culture, S. CUSHMAN (*Agr. Massachusetts*, 1897, pp. 97-116).—A popular address on this subject.

DAIRY FARMING—DAIRYING.

On milk "signs" in dairy cows, C. NÖRNER (*Milch Ztg.*, 27 (1898), No. 16, pp. 722-725; 47, pp. 739-741).—The author reviews the various rules or points (*Milchzeichen*) for judging of the merits of milch cows, which have been laid down by different reputable writers from time to time. These "signs" are based upon a variety of characteristics, some on the relative size and shape of the different parts of the cow's body, others on the hair, others on the size and conformation of the udder, escutcheon, milk veins, etc. Following a summary of them, the author gives a critical discussion of their merits, based upon observations and measurements made by himself as well as on the studies of others. He concludes that most of these signs are wholly useless for judging the productiveness of a cow. He lays the most stress upon what he terms a "maternal appearance" both in bodily form and in character. The form of the udder is considered an important point, and also the size of the milk vein; but it is pointed out that a large udder is not always a sign of productiveness. "In the case of good milkers the skin of the udder has the appearance of having been dusted over with bran and has a fatty feeling." No importance is attached to the escutcheon, and this is said to be the general conclusion of European authorities.

In conclusion, the body measurements are given of the best cow in the Province of Brandenburg, as shown by a trial milking for one year. This cow was small and unsightly in appearance, and gave no external indication of so great productiveness.

Cotton-seed feed as a hay substitute for milch cows, J. B. LINDSEY, E. B. HOLLAND, and B. K. JONES (*Massachusetts Hatch Sta. Rpt.* 1897, pp. 79-101).—Two experiments are reported on the substitution of cotton-seed feed for hay, using 6 cows in each experiment. In the first experiment the commercial mixture, said to consist of 1 part of cotton-seed meal to 4 parts of hulls, was used, and in the second experiment the materials were mixed at the station in this proportion. Preliminary to the experiments 6 digestion trials of cotton-seed feed were made with sheep. The details of these trials are not given, but the average is tabulated, together with the results of similar determinations made at other stations. "The cotton-seed feed appeared to agree

better with the sheep when fed in connection with hay than when fed by itself. In the latter case, at the close of the period the sheep began to show signs of digestive disturbances, which would certainly have become quite pronounced had the feeding been continued much longer."

The first feeding experiment was made during April and May and included 2 periods of 21 days each, with a transition period. The second experiment lasted from October 6 to December 15, the time being divided into 2 periods, with a transition period of 2 weeks. In each experiment the cows were divided into 2 lots, one lot being fed the cotton-seed feed ration and the other the hay ration in the first period, and the feeding reversed in the second period. In the first experiment like amounts of cotton-seed feed and hay were fed with a constant basal ration, but in the second experiment 2 or 3 lbs. of hay was fed with the cotton-seed feed, the basal ration of grain being constant as before.

The results for the individual cows, together with the composition of the feeding stuffs and the milk, are tabulated. In computing the financial results, hay and cotton-seed feed are both rated at \$15 per ton. A summary of the results of the 2 experiments is given in the following table:

Comparison of cotton-seed feed with hay for milch cows.

	Total yield of milk.	Total yield of solids.	Total yield of fat.	Digestible matter required to pro- duce—		Average cost of food per—	
				100lbs. of milk.	1 lb. of butter. ^a	100lbs. of milk.	1 lb. of butter.
				<i>Pounds.</i>	<i>Pounds.</i>	<i>Cents.</i>	<i>Cents.</i>
First experiment:							
Cotton-seed feed	2,574.58	366.87	133.33	64.40	10.68	94.70	15.49
Hay	2,483.21	346.92	119.00	68.49	12.27	100.10	17.94
Second experiment:							
Cotton-seed feed	548.73	76.10	26.18	70.90	12.77	110.6	20.10
Hay	574.99	79.90	27.02	66.90	12.18	104.9	19.33
Summary of 2 experiments:							
Cotton-seed feed	5,867.00	823.50	290.4	67.65	11.72	102.6	17.79
Hay	5,933.00	826.30	281.1	67.69	12.22	102.5	18.63

^a Calculated from the milk fat.

"[In the first experiment] the cotton-seed feed ration gave a slightly larger amount of milk than the hay ration. A 5.4 per cent increase in the amount of total solids is also noted, while fully 10 per cent more butter fat was produced by the cotton-seed ration. This latter result could hardly have been expected. . . . A part of the decrease in the amount of milk, solids, and fat produced by the hay ration can be accounted for in the sudden shrinkage of cow 5, . . . showing a shrinkage of 31 per cent in yield of milk [on hay] from that produced in the previous period. . . ."

"[In the second experiment, with fresh cows] the results are the reverse of those obtained in the first test, the hay period yielding several per cent more milk, milk solids, and fat. Our observations of the animals from day to day during the trial indicated that the cotton-seed feed ration was falling slightly behind the hay ration. . . . The cotton-seed rations slightly increased the cost of the milk and butter."

In conclusion, the authors state that while the 2 experiments have shown cotton-seed feed to give as large milk and butter yields as

low a cost as a good quality of hay, they believe it to require more energy for digestion than hay, and that when fed for any length of time it would have a tendency to induce digestive disturbances. It is not recommended for Massachusetts farmers in place of hay unless it can be bought cheaper than hay, in which case it is suggested that one half of the hay may be replaced by the feed.

A study of rations fed to milch cows in Connecticut, W. O. ATWATER and C. S. PHELPS (*Connecticut Storrs Sta. Rpt. 1897, pp. 17-66*).—This is a continuation of the study of rations fed by practical dairymen in the State (E. S. R., 9, p. 786), being a report for the fifth winter's work. The rations of 4 herds were studied, the period of observation lasting 12 days, and then after an interval of about 2 weeks, in which the suggested rations were introduced, the study was repeated. "The main idea was to change the feeding in such a manner as would not only give a ration with a narrow nutritive ratio, but to vary this for the different animals of the herd in accordance with their milk production." The details of the study are tabulated, and the results are discussed at considerable length. The results for the 4 herds are briefly summarized in the following table, the first test showing the rations which were being fed by the dairymen, and the second test those suggested by the station:

Original and suggested rations fed to dairy cows.

	Total amount of food.	Digestible nutrients and fuel value.					Cost.	Value of obtainable manure.	Net cost.
		Protein.	Fat.	Carbohy- drates.	Fuel value.	Nutri- tive ratio.			
	Lbs.	Lbs.	Lb.	Lbs.	Calories.		Cents.	Cents.	Cents.

"[With herd J] the average daily cost of the ration was reduced from 16.3 cts. to 14.6 cts. The average daily yield of milk was less by 0.5 lb. in the second test than in the first, but the daily yield of butter was larger by 0.05 lb. The total cost of food to produce 100 lbs. of milk was reduced 7 cts., and the cost of feed for 1 lb. of butter was reduced 3 cts. in the second test. . . .

"[With herd K] the total cost of the first ration was 15.6 cts., and of the second ration 14.9 cts. per cow per day. The second grain ration cost 0.4 ct. per day more than the first, while the coarse fodders cost about 1 ct. less in the case of the second ration. The average milk yield was essentially the same in each of the tests, while the yield of butter fat was 0.07 lb. more per day in the case of the second ration. . . .

"The second ration [of herd L] was an exceptionally heavy one in protein, [and] the herd had larger quantities of protein than are there recommended for cows with

a corresponding milk flow. Notwithstanding the heavy protein ration fed, the average milk flow for the 9 cows in the second test was 1.3 lbs. per day greater than in the first test, while the cost of the second ration was 0.6 ct. more per day. This farmer was producing milk for the Boston market, and at the average price (3 cts. per quart) the increase in milk flow in the case of the second ration more than covered the additional cost. For most of the cows, however, the increase was very slight, and we are inclined to doubt if the feeding of as large quantities of protein as were here used would be economical, except in the case of very heavy milkers. . . .

"The ration fed [to herd M] in the first test was as heavy and as large in protein as is commonly recommended for cows of this weight. The protein was purposely increased by a large amount (1 lb. per day) in the second test, and the nutritive ratio was thus made quite narrow. Both rations seem to have been well eaten by the cows, although the milk flow in the second test for some reason dropped off to an unusual degree. The general tendency of rations high in protein in nearly all of our experiments has been to keep up the milk flow and lessen the natural shrinkage. The average percentage of butter fat in the second test was increased by 0.4 per cent. This made the total yields of butter fat about equal in the two tests. The total cost of the second ration was slightly less than that of the first ration. For the production of milk this second ration, however, proved unprofitable."

During the five seasons' work 45 rations have been studied. These included "32 which were found in actual use by some of the more intelligent and successful dairymen in the State, and 13 rations which were proposed by the station to test the effect of larger amounts of protein than those used by the feeders. These 13 tests with the narrower rations were made after the studies of the actual feeding practice in the same number of cases." The result of these studies are variously summarized in tables.

Averages of rations fed by Connecticut dairymen, with daily yields of milk and butter and percentages of fat.

Rations.	Digestible nutrients and fuel values.					Daily milk yield.	Average fat content of milk.	Daily butter yield. ^a
	Protein.	Fat.	Carbohydrates.	Fuel value.	Nutritive ratio.			
	Lbs.	Lb.	Lbs.	Cal.		Lbs.	Per ct.	Lbs.
Average of all the rations (45).....	2.08	0.72	11.21	27,750	1:6.5	17.6	4.8	0.97
Average of 32 rations found in actual practice.....	1.97	.73	11.57	28,250	1:7.0	17.5	4.8	.96
Average of rations containing 2 pounds or less of digestible protein per day, as fed 16 herds (226 cows) in actual practice.....	1.62	.65	11.37	26,900	1:8.1	16.3	4.7	.87
Average of rations containing more than 2 pounds of digestible protein per day, as fed 16 herds (227 cows) in actual practice.....	2.32	.81	11.77	29,600	1:5.9	18.7	4.9	1.05
Average of 11 wide rations (first test) as found in use.....	1.78	.64	11.86	28,100	1:7.7	18.0	4.7	1.00
Average of 11 narrower rations (second test) proposed by the Station.....	2.40	.67	10.37	26,600	1:5.1	18.2	4.9	1.04

^a Calculated.

"The 45 rations as fed contained from 1.15 to 3.26 lbs. of digestible protein, averaging 2.1 lbs.; and the fuel values ranged from 21,150 to 35,150 calories, averaging 27,750 calories. The nutritive ratios ranged from 1:3.3 to 1:11.3, with an average of 1:6.5. . . .

"In the 32 tests of actual feeding practice the average ration per cow per day supplied from 1.15 to 2.70 lbs., averaging 2 lbs. of digestible protein; while the range of fuel values was from 21,150 to 35,150, averaging 28,250 calories. The nutritive ratios of these rations ranged from 1:4.5 to 1:11.3, averaging 1:7.0. . . .

"The advantage of rations with liberal quantities of protein is quite clearly shown when the herds are divided into two groups according to the amounts of protein in the rations fed. The group composed of those herds receiving 2 lbs. or less of digestible protein per cow per day produced on the average 16.3 lbs. of milk and 0.87 lb. of butter per day, while the group receiving more than 2 lbs. of digestible protein per cow per day averaged 18.7 lbs. of milk and 1.05 lbs. of butter. This means that the herds which were fed the larger quantities of protein produced on the average 15 per cent more milk and 20 per cent more butter per cow than those fed the smaller quantities of protein. . . .

"It is impracticable to compare accurately the costs of the rations fed throughout these 32 tests, but the general results of our experiments indicate that the rations with relatively large proportions of protein are cheaper than those containing relatively smaller quantities. . . .

"Our studies tend to point more and more to the conclusion that rations should be compounded in accordance with the milk flow rather than in accordance with the live weight of the animals. If the milk flow is uniform, the feed need not vary much for variations of 100 to 200 lbs. live weight, but with an increase in the milk flow the size of the ration should be larger, and especially the protein should be increased both in total quantity and relatively, in order to meet the increased demands on the system of the animal."

Nitrogenous feeding stuffs, and feeding formulas for dairy cows, W. O. ATWATER and C. S. PHELPS (*Connecticut Storrs Sta. Rpt. 1897, pp. 67-129*).—This is quite a general article discussing the food supply of the farm, composition and digestibility of feeding stuffs, energy required for digestion, food requirements of the animal organism, manurial value of nitrogenous feeding stuffs, influence of food upon the composition of cows' milk, with a summary of experiments on this point made by different stations, and feeding standards or formulas.

The conclusion from the experiments summarized on the effect of food on milk is that—

"Liberal amounts of protein and narrow rations tend to increase the flow of milk and to lessen the natural shrinkage due to advanced period of lactation.

"As to the influence of nitrogenous feeding stuffs on the composition of milk, the results of the majority of the experiments here reported indicate that the narrow rations tended to increase the percentages of total solids and of fat in the milk to a slight degree. A rise of from 0.2 to 0.6 in the average percentages of fat in milk in favor of the narrow rations is seen in at least 4 of the experiments recorded. The individuality of the cow, however, seemed to be an important factor. While in the case of some cows a considerable change in the percentage of solids and of fat was noticed, in other cases there seemed to be little or no change.

"The percentages of fat in the total solids of the milk was larger in at least 4 of the experiments where the narrow rations were fed—that is, the proportion of fat to solids-not-fat seemed to be increased in these instances by the use of narrow rations.

"With regard to the relative profit from the use of the narrow and the wide rations, there seems to be a diversity of opinion, but the general verdict of the experiments here recorded is in favor of the liberal use of nitrogenous feeding stuffs from the standpoint of profit, especially in the Eastern States."

The effect of some undetermined factors in experiments of this kind, as short periods and the total quantity of food, is considered, and the application and importance of metabolism experiments in the study of this question is emphasized.

The question of feeding standards is discussed at considerable length and the point is made that "a physiological standard or a formula for profit to feed in all cases is not only irrational but impossible." It is believed that the amount of food should be varied in proportion to the milk yield and to suit the stage of lactation. In accordance with this belief 6 rations are proposed "with the plan in view of utilizing home-grown nitrogenous feeding stuffs and of supplementing these mainly by the addition of concentrated nitrogenous feeds, the latter to be increased in accordance with the milk production." In the case of each ration a basal ration is given for cows producing from 10 to 20 lbs. of milk per day. For all cows giving over 20 lbs. of milk per day there is added to this basal ration 1 lb. of a protein mixture (furnishing 0.3 lb. of digestible protein) for each 5 lbs. increase in the milk flow. The rations are calculated for cows weighing from 750 to 950 lbs. and would probably require to be increased for heavier cows. In the case of each ration the components of the basal ration and the protein mixture, with the amounts of digestible nutrients furnished, are given. The rations are adapted to different conditions with respect to the feeding stuffs grown on the farm.

Dairy rations, F. L. KENT (*Oregon Sta. Bul. 51, pp. 12-16*).—Four cows were fed for periods of 15 days each on the following rations:

- Ration 1. Corn silage 25 lbs., clover hay 10 lbs., bran 6 lbs.
- Ration 2. Corn silage 25 lbs., clover hay 10 lbs., bran 5 lbs., oat chop 3 lbs.
- Ration 3. Corn silage 40 lbs., clover hay 5 lbs.
- Ration 4. Clover hay 15 lbs., bran 5 lbs., oat chop 2 lbs., carrots 8 lbs.
- Ration 5. Clover hay 15 lbs., bran 5 lbs., oat chop 3 lbs., shorts 2 lbs.

"Of the 5 rations fed, No. 1 . . . is shown by the tables to be the most satisfactory. The cost of a pound of butter fat is low, only 10.4 cts. at a time when butter was worth 25 cts. per pound in the market. . . . In rations 1 and 2, where silage was fed in connection with grain and hay, butter fat was produced at a cost of 10.4 cts. and 12.8 cts. respectively. In rations 4 and 5, where the silage was omitted and larger quantities of hay and grain fed, the cost per pound of butter fat was 16.1 cts. and 17.4 cts. respectively."

Root feeding, F. L. KENT (*Oregon Sta. Bul. 51, pp. 17-19*).—Feeding a constant basal ration of clover hay, silage, and grain, a comparison was made of beets, carrots, and mangel-wurzels, feeding about 24 lbs. of each. Each ration was fed to 4 cows for 4 weeks. There were no differences in the yield and cost of butter fat on the 3 rations which could be attributed to the different root crops.

"Very little difference was noticeable in the quality of the butter from the different rations, especially between the rations consisting largely of carrots and sugar beets. That from the ration consisting largely of mangels was not quite so high in flavor, however, as the butter from the other 2 rations."

Experiments on the effect on butter of feeding cotton-seed and sesame-oil cake, T. E. THORPE (*Analyst*, 23 (1898), Oct., pp. 255-259).—These experiments were made for the British Board of Agriculture by the Southeastern Agricultural College at Wye, for the purpose of determining whether and to what extent the substances giving the cotton-seed and sesame-oil reactions might be found in the butter made from the milk of cows fed on cotton-seed and sesame-oil cakes."

Twelve cows were fed in 4 lots during 6 periods, commencing February 16 and ending May 25. A part or the whole of the linseed cake in the basal ration was replaced in different periods by cotton-seed cake or sesame cake, as high as 7 lbs. of each being fed per cow daily, which was the limit to the amount the cows would eat. Butter was made from the milk and samples were tested for the cotton-seed oil and sesame oil reactions. They were also compared with butter made with the addition of 1, 2, and 5 per cent of 4 representative samples of cotton-seed oil.

The general conclusions from the experiment are summarized as follows:

"(1) Cows fed on cotton-seed oil cake produce milk the butter fat of which gives cotton-seed oil reactions.

"(2) The reactions appear when the cows receive only a small quantity of cake. They increase somewhat with continuous feeding, but apparently can not be carried beyond a certain point, even when the amount of cake is increased to the full limit which the cows under ordinary circumstances care to eat.

"(3) The reacting substance passes into the milk within less than 24 hours after the cake feeding begins, and continues to do so for several days after it has been dropped.

"(4) The reactions vary in intensity in individual cows, but do not in any case much exceed those given by 1 per cent of cotton-seed oil mixed with butter. The presumption is, therefore, that in butter made in the ordinary way from the mixed milks of several cows the reaction would, as a rule, be less than that due to the presence of 1 per cent of the oil, and experiment shows that this is actually the case.

"(5) As feeding with cotton-seed oil cake gives butter affording analytical data tending to differ from rather than to approach to those given by margarine, it appears to be possible in most cases to differentiate between the cotton-seed oil reaction due to feeding on cotton-seed oil cake and that produced by any considerable admixture of margarine containing cotton-seed oil with butter.

"(6) The butter from the milk of cows fed on sesame-oil cake gives no sesame-oil reaction, even after more than 5 months' continuous feeding up to as large a quantity as the cows will take."

The changes in butter due to feeding fat, G. BAUMERT and F. FALKE (*Ztschr. Untersuch. Nahr. u. Genussmtl.*, 1898, No. 10, pp. 665-678).—This experiment was made at the agricultural institute at Halle. Two cows were fed from January 17 to May 7, 1897, in 5 periods of 20 days each, the first half of each period being regarded as preparatory. A constant basal ration was fed throughout the experiment. To this was added per cow 700 to 900 gm. of sesame oil in the second period; 550 to 700 gm. of cocoanut oil in the third period, and 500 gm. of almond oil in the fourth period. The oil was given as in Soxhlet's experiments (*E. S. R.*, 8, p. 1016), in the form of an emulsion as a warm drink. Sweet

cream butter was made from the milk of each cow daily. No data are given as to the yield and composition of the milk, but the results are tabulated of the examination of 32 samples of butter produced in the first period, 44 in the second period, 36 in the third period, 34 in the fourth period, and 32 in the last period. The results are summarized in the following table:

Butter produced on basal ration and with the addition of sesame, cocoanut, and almond oils.

Period.		Melting point of butter.	Index of refraction.		Köttstorfer number.		Volatile fatty acids.		Iodin number.	
			Of oil fed.	Of butter.	Of oil fed.	Of butter.	Of oil fed.	Of butter.	Of oil fed.	Of butter.
1	Basal ration:	Deg. C.								
	Swiss cow	34.16		-1.7	224		31.0		44.3	
	Dutch cow	33.96		+2.4	223		29.5		45.0	
2	Sesame oil:									
	Swiss cow	37.00	17.6	+5.6	190	204	0.4	16.9	116	53.9
	Dutch cow	36.76	17.6	+5.4	190	206	0.4	15.7	116	52.9
3	Cocoanut oil:									
	Swiss cow	33.58	-9.2	-0.5	255	237	8.0	20.6	9	37.1
	Dutch cow	34.76	-9.2	-0.6	255	230	8.0	18.6	9	35.2
4	Almond oil:									
	Swiss cow	34.28	+13.6	+3.6	195	210	0.0	19.7	98	50.9
	Dutch cow	34.50	+13.6	+4.3	195	207	0.0	15.3	98	53.9
5	Basal ration:									
	Swiss cow	34.50		+3.0		218		22.0		41.2
	Dutch cow	35.15		+3.6		216		24.4		44.5

The sesame oil had a marked influence on the appearance and taste of the milk and increased the index of refraction, diminished the Köttstorfer number and the volatile fatty acids, and increased the iodine number of the butter. A test for sesame oil with furfural and hydrochloric acid gave no reaction. The butter produced on cocoanut oil was normal in appearance, but had an unmistakable taste of cocoanut oil. The index of refraction of the butter was materially diminished, the Köttstorfer number was materially and the volatile fatty acids slightly increased, and the iodine number was noticeably diminished. On almond oil the butter showed a positive increase in the index of refraction, the Köttstorfer number diminished slightly, and the iodine number increased.

The authors conclude that the feeding of oils not only greatly changed the butter, but that the changes followed in general the characteristics of the oils themselves. "In other words, in feeding sesame oil, cocoanut oil, and almond oil butter fat was produced which corresponded in its chemical properties to artificial mixtures of butter with these 3 oils." The authors go so far as to say that in the light of the above investigations the feeding of such oils would constitute "an adulteration of the butter within the animal's body."

Fresh vs. stripper cow butter, F. L. KENT (*Oregon Sta. Bul. 51, pp. 20, 21*).—In an experiment of about 5 days' duration the milk of 11 cows averaging 121 days from calf was compared with that of 4 cows averaging 283 days from calf.

"So far as this short experiment goes, it shows that the milk from comparatively fresh cows gives up its cream more readily even with a separator than does milk

from cows well along in the period of lactation. It also shows that butter made from the milk of cows which have been in milk for a considerable period of time is slightly inferior to that made from the milk of cows which are comparatively fresh."

A few experiments concerning the hardness of butter, H. ATWOOD (*West Virginia Farm Review*, 6 (1898), No. 11, pp. 355, 356).—Fifty-two and one-half pounds of sweet Cooley cream was divided into 2 equal parts, one being warmed gradually to 56° and churned and the other warmed gradually to 65°, kept at that temperature 2 hours, and then churned. It was found that the butter from the cream churned at 65° came and remained softer than that from the cream churned at 56°. The hardness of the butter was determined by dropping a small glass tube filled with mercury upon the butter and observing the penetration. In another experiment both lots of cream were warmed considerably above the proper churning temperature and then cooled quickly. One part was churned at once and the other was allowed to remain at the proper churning temperature for 4½ hours and then churned. "The butter from the cream which was churned immediately after being cooled came softer and remained softer than the other."

Studies on the formation of holes in Emmenthaler cheese, O. JENSEN (*Centbl. Bakt. u. Par., 2. Abt., 4* (1898), No. 6, pp. 217-222; 7, pp. 265-275; 8, pp. 325-331).—The author reviews the theories in regard to the cause of these holes and reports investigations to test their accuracy. The conclusions which he reaches are as follows: (1) The normal holes in Emmenthaler cheese are not produced by the same agents as swelling or by yeasts or obligate anaerobic bacteria, but by the agents which cause normal ripening, i. e., lactic-acid producing organisms. (2) The gas which is the immediate cause of the holes is not produced at the cost of the milk sugar, but from the nitrogenous substances. (3) The lactic-acid organisms of cheese can, under certain conditions, form traces of carbon dioxid from nitrogenous substances, and these traces are the cause of the normal formation of holes in Emmenthaler cheese.

The cause of the ripening of Emmenthaler cheese, E. VON FREUDENREICH (*Landw. Jahrb. Schweiz, 11* (1897), pp. 85-101; and *Centbl. Bakt. u. Par., 2. Abt., 4* (1898), No. 5, pp. 170-174; 6, pp. 223-230; 7, pp. 276-281).—Two cheeses were examined bacteriologically with results similar to those found on previous occasions. Numerous lactic acid micro-organisms were found, with only a few liquefying organisms. Experiments in inoculating Ducleaux' liquefying organism, tyrothrix, into cheese, showed as formerly that the organism can not increase in cheese but, on the contrary, decrease in numbers. Various experiments are reported with cheese made from pasteurized milk which was inoculated with cultures of lactic-acid bacteria, liquefying bacteria, and anaerobic bacilli. These experiments, the author concludes, indicate that the lactic-acid organism plays a principal rôle in the ripening of cheese, since ripening took place when the lactic-acid organisms were

used alone or combined with other forms, and the cheese did not ripen with the liquefying bacilli alone.

As the pasteurized milk was not entirely free from micro-organisms, experiments were undertaken with milk which was obtained under the greatest precautions in the hope of securing aseptic milk. This milk was found, however, to contain from 92 to 500 bacteria per cubic centimeter. The cheese molded, although it was kept under a sterilized bell glass, and was then scraped and dipped in a solution of paraffin, which, in some cases, promoted the growth of an anaerobic bacillus. This, however, is not believed to have interfered with the experiment. "These experiments indicate anew that the ripening of cheese is invariably associated with the presence of lactic-acid organisms and under the exclusion of so-called tyrothrix bacilli; the latter were not to be found in the ripened portion of the cheese or on the surface."

Studies were then made on the effect of lactic acid in changing the casein, to determine definitely whether the change in the casein was due to the action of the lactic organisms or to the acid produced. The lactic acid produced in the milk cultures was neutralized by calcium carbonate, the bottles being frequently shaken for this purpose. The results showed that the change in the casein could not be attributed to the action of lactic acid.

Finally the results are recorded of 12 experiments in inoculating into milk various pure cultures of micro-organisms isolated from cheese.

The author's final conclusion is that the lactic-acid organisms, especially those isolated from cheese, are able to dissolve and decompose casein, and that there is no further ground for doubt that the cause of the ripening of hard cheese is to be found in the lactic organisms. He suggests that, knowing the cause of the ripening, a practical application may be made as has been done in butter making in using pure cultures for ripening cream.

The fungi taking part in cheese ripening. O. JOHAN-OLSEN (*Centbl. Bakt. u. Par., 2. Abt., 4 (1898), No. 5, pp. 161-169, pls. 6*).—The author gives a condensed account of his studies on the cause of the ripening of Gammelost, a Norwegian cheese made from pasteurized skim milk, and the use of a mixture of pure cultures in the manufacture of this cheese. From the various forms of micro-organisms found in different samples of the cheese, it was found by practical experiments extending over quite a period that the best results were obtained by the use of pure cultures of lactic-acid organisms from Gammelost cheese, *Chlamydomucor casei*, *Mucor casei* I, and *Penicillium aromaticum casei*. The character of the cheese could be changed at will by partial changes in the organisms used. The method of making the cheese by the old and the new ways is described. The cheese made with the pure cultures was much more uniform in quality, kept better, had a finer flavor, and a less objectionable odor. The ripening can be so well regulated that less than 10 per cent of the cheeses are inferior. These pure cultures are

coming to be used in practice, about 15,000 kg. of Gammelost being made with pure cultures the past year, it is estimated.

In a similar way the author has worked out pure cultures for making Gorgonzola, Camembert, Roquefort, and Fromage Norwegian cheeses, although these are not described in the article.

The action of rennet ferment, E. VON FREUDENREICH (*Landw. Jahrb. Schweiz*, 11 (1897), pp. 102-116; and *Centbl. Bact. u. Par.*, 2. Abt., 4 (1898), No. 8, pp. 309-335).—In order to obtain germ-free rennet the author made experiments with the use of various antiseptics, i. e., chloroform, potassium bicarbonate, thymol, salol, glycerin, and formic aldehyde. An artificial preparation of rennet in the form of rennet tablets was used. An aqueous solution of formic aldehyde (0.5 to 1 per cent) was the only disinfectant which gave satisfactory results. Chloroform did not diminish the action of the rennet but failed to sterilize it completely. Potassium bicarbonate in 0.005 solution did not sterilize and materially weakened the action of the rennet. Thymol sterilized the preparation but prevented the action of the ferment. The same was true of formic aldehyde vapor.

The best means of preparing a germ-free rennet was found to be filtering it through a Chamberland porcelain filter. This weakens the action of the rennet solution somewhat, which can be remedied by starting with a stronger solution. The strength of this filtered rennet solution was weakened by keeping.

Experiments were made with this germ-free rennet on the curdling of pasteurized milk, the milk being heated for different lengths of time at from 68 to 90° C. Milk heated to 68° for 15 minutes curdled well with rennet, but if the heating was continued for an hour the curdling was materially diminished, although not entirely prevented. Continued heating at 70° or over had a decidedly unfavorable effect upon the curdling. The conclusion is that where it is desirable to pasteurize milk it may be done without spoiling the milk for cheese making.

Dairy bulletin by the Dairy School, Guelph (*Ontario Agr. Col. and Expt. Farm Bul.* 107, pp. 32).—A popular bulletin on methods of disposal of sewage from creameries and cheese factories, the testing and handling of milk, and the making of butter and cheese.

Report on the chemical examination of two hundred individual specimens of human milk, V. ADRIANCE and J. S. ADRIANCE (*New York*, 1898, pp. 42; *abs. in Jour. Soc. Chem. Ind.*, 17 (1898), No. 7, pp. 686).

Composition and food value of cheeses, BALLAND (*Compt. Rend. Acad. Sci. Paris*, 127 (1898), No. 22, pp. 879-881).—A brief extract of a paper presented before the society.

Milch cows, structure as relating to production, G. M. TWITCHELL (*Agr. Massachusetts*, 1897, pp. 23-37).—This is a popular paper delivered before the Massachusetts Board of Agriculture on the importance of type in the selection and breeding of dairy cows.

The source of milk fat, R. WARINGTON (*Jour. Roy. Agr. Soc. England*, 3. ser., 9 (1898), pt. 2, No. 34, pp. 317-323).—This article consists principally of a review of the experiment in milk production on fat-free food at the New York State Station (E. S.

R., 9, p. 1683), from which the author concludes that "the dairy farmer need no longer feel the necessity for supplying his cows at all costs with a highly nitrogenous diet; a liberal ration of cereal corn, including bran, is apparently sufficient to yield a full supply of milk and butter."

Is the fat of the food directly transmitted to the milk? WINTERNITZ (*München. Med. Wchenschr.*, 44 (1897), No. 30; *abs. in Ztschr. Fleisch und Milchhyg.*, 8 (1898), No. 11, p. 200).—The author fed iodine fat to a goat and examined the milk for iodine. The results, he believes, indicate that the food fat is transmitted to the body fat or milk.

Abnormal milk (*Milch Ztg.*, 27 (1898), No. 48, p. 760).—A cow at the agricultural academy at Poppelsdorf, in the last stages of lactation, gave milk with from 6.5 to 7 per cent of fat. When she was nearly dry she gave 60 gm. of milk at night and 100 gm. in the morning which contained 42.1 per cent of solids, 25.57 per cent of fat, 16.53 per cent of solids-not-fat, and 2.32 per cent of sugar. She was found unsound when slaughtered.

Milk supply and the public health, W. T. SEDGEWICK (*Agr. Massachusetts*, 1897, pp. 46-54).—This is a popular paper delivered before a public meeting of the Massachusetts Board of Agriculture, in which the character and sources of milk contamination are discussed and suggestions made on the production and handling of milk from a sanitary standpoint.

The present status of the "milk ice" question (*Milch Ztg.*, 27 (1898), No. 49, p. 776).—A commission sent by the Mark Brandenburg to investigate the milk ice trade in Copenhagen (E. S. R., 9, p. 581) reports that at present about 18,000 liters are sold daily. There has been no difficulty in introducing milk ice, but on the contrary the demand at times has exceeded the supply. It is preferred to other milk by the customers because the chilling as soon as possible after milking preserves the original aroma and hinders the action of micro-organisms. It is of advantage to dealers, as surplus milk can be stored for some time and used as needed.

Why milk sours and how souring can be prevented or at least delayed, G. M. WHITAKER (*Agr. Massachusetts*, 1897, pp. 48-53).—This treats in a popular manner of the souring of milk and the value of cleanliness and prompt cooling as preventives.

Pasteurization of milk, F. E. EMERY (*North Carolina Sta. Bul.* 148, pp. 300-304, fig. 1, *dgm.* 1).—A popular explanation of pasteurization with an illustrated description of a pasteurizing apparatus devised at the station. The apparatus consists of a large galvanized iron box with a rack for supporting the jars or cans and heated by live steam or a stove. A diagram shows the temperature of the milk and the water in the box during two trials.

The effect of several substances on the curdling of milk, T. BOKORNEY (*Milch Ztg.*, 27 (1898), No. 49, pp. 769, 770).—Experiments with a number of common and some new milk preservatives. Most of the new substances were ineffective.

Observations on the ripening of cream, W. GRANSKY (*Milch Ztg.*, 27 (1898), No. 47, pp. 741-742).—Data covering a little over 2 weeks, collected at the dairy institute at Hameln.

Effect on the quality of butter of feeding oil cakes (*Milch Ztg.*, 27 (1898), No. 46, pp. 721-722).—An account of English experiments noted elsewhere (p. 685).

Cost of production of butter, T. L. HAECKER (*Wisconsin Dairymen's Assoc. Rpt.* 1898, pp. 127-142).—A popular address.

VETERINARY SCIENCE AND PRACTICE.

Preliminary report upon a comparative study of tubercle bacilli from man (sputum) and from cattle, T. SMITH (*Agr. Massachusetts*, 1897, pp. 564-581).—The author's observation that there were differences in the lesions produced in guinea pigs by the inoculation of tubercular products of cattle and from the sputum of human beings

led to an extended investigation of the subject. Some of the earlier experiments have been previously reported.¹

In the present publication 12 experiments with cattle are described in considerable detail. Six animals were inoculated with human bacilli, 5 with bovine bacilli, and 1 with swine bacilli. In all cases cultures isolated by the author were used. Inoculations were first made on guinea pigs, and from them after 3 to 6 weeks cultures on dog serum were made. These were tested upon rabbits and guinea pigs and lastly on the cattle. In all the tests the experimental conditions were kept as nearly uniform as possible. Of the 6 cases inoculated with bacilli from sputum 1 showed no disease, 2 very slight lesions, and 3 only local lesions without dissemination. Of the 5 cases inoculated with bovine bacilli, 2 died of generalized disease, 2 showed extensive lesions, and 1 less extensive lesions. The animal inoculated with swine bacilli, which the author remarks were probably originally bovine, showed less extensive lesions than the animals inoculated with bovine bacilli.

"We may now maintain that bovine tubercle bacilli and human bacilli as found in sputum are not identical. The difference in their action upon cattle is reinforced by certain differences in the bacilli themselves and their effect upon rabbits. . . .

"What the significance of these divergencies is, what influence they have upon the transmissibility of the disease from cattle to man, we are unable at present to state with any degree of certainty. That they do have some effect must be admitted in view of results of studies upon other species of pathogenic bacteria. Their precise bearing needs careful investigation.

"These studies will, I think, warrant one inference, however; that is, that human sputum can not be regarded as specially dangerous to cattle, nor can it be looked upon as a factor in the introduction of tuberculosis into a healthy herd of cattle. Even if the tubercle bacilli of cattle and of man are very closely related and have the same ancestry, as we all must admit, if we regard the two as mere varieties, which may eventually, under very favorable conditions, pass one into the other, the condition in which the bacillus leaves the lungs in sputum is evidently such as to interfere, under ordinary circumstances, with any development in the bovine body. It would fall a speedy prey to destruction.

"I refrain, for obvious reasons, from drawing the conclusions that all human tubercle bacilli are like those existing in the sputum of phthisis."

A comparative study of bovine tubercle bacilli and of human bacilli from sputum, T. SMITH (*Jour. Exptl. Med.*, 3 (1898), No. 4-5, pp. 451-511).—In this publication the author describes the experiments noted above, and in addition reports comparative tests of bovine tubercle bacilli and bacilli from human sputum upon rabbits, gray mice, and pigeons.

"The foregoing experiments, while they show unmistakably the close relationship existing among the various cultures studied, nevertheless justify us, if only to guide and stimulate further study, in establishing a distinctively human or sputum and a bovine variety of the tubercle bacillus. . . . The characters upon which the bovine variety may be based reside, morphologically, in the invariably short, straight

¹Trans. Assoc. Amer. Physicians, 1896, pp. 75-93. U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1895-96, pp. 149-161 (E. S. R., 9, p. 889).

form, and in the greater resistance of this form to modifying influences of culture-media; biologically, in a greater resistance to artificial cultivation and in a much greater pathogenic activity toward rabbits, guinea pigs, and cattle.

"There is proof, furthermore, of the existence of slightly varying characters even within the varieties proposed. Among the bovine forms studied slight variations in virulence were noticeable. Among the sputum forms, variations in size, in capacity for cultivation, and in pathogenic activity have been observed. . . . In spite of these variations, mammalian tubercle bacilli may still be considered as forming a fairly compact group when compared with the tubercle bacilli of birds, which are but slightly virulent toward the guinea pig, so susceptible to the mammalian type. . . . The bovine type differs from the human bacilli in a far less saprophytic growth. In the pathological secretion and in the caseous masses the bacilli are relatively scarce. This difference may be a result of their adaptation to the bovine body, in which cavities of the lungs and catarrh of the air tubes are far less common. In other words, certain differences in the type of reaction tend in the one case to make the human bacillus more saprophytic, the bovine more parasitic."

A study of normal temperatures and the tuberculin test, C. E. MARSHALL (*Michigan Sta. Bul. 159, pp. 317-396*).—A general discussion of tuberculin and its use is followed by a detailed report of a study of the variations in normal temperature of cattle and a comparison of these results with the variations in temperature after injecting tuberculin. It was found that normal maximum temperatures varied from a fraction of a degree to over 5°.

"Owing to this great variation in normal maximal temperatures, we feel justified in bidding caution to all operators in the tuberculin test. The too prevalent method of finding the maximal temperatures of the day of and the day after injection and condemning animals in accordance with this standard, without any further investigation, may be the means of unnecessary destruction of property. There are cases where this would be legitimately allowable, as we shall see later in a survey of reactions, but when it is applied irrespective of other features it can not be justified. Where there is a possibility of 5° of variation in normal maximal temperatures, 2° can not be taken as the sole criterion for placing the stamp of 'tuberculous' upon an animal."

Sudden changes in temperature, the influence of seasons or atmospheric temperature upon the temperature of animals, time of day when maximum and minimum temperatures occur, and whether temperatures higher or lower occur on the second day of the test are also discussed with reference to the temperature records kept at the station.

In summarizing the discussion the following tentative conclusions are advanced:

- "(1) Tuberculin is the best diagnostic known for tuberclosis.
- "(2) Tuberculin itself may be infallible, but its application and interpretation are not.
- "(3) An arbitrary point of condemnation is unwarranted.
- "(4) To succeed in eradicating tuberculosis from a herd, the tuberculin test must be applied persistently at intervals for as yet an undetermined time.
- "(5) The slaughtering of animals reacting to tuberculin is not justified, unless the physical condition of the animal confirms the tuberculin test and makes it a wise precaution. Reacting animals should be isolated. Should a second test diagnose tuberculosis, slaughter is possibly made justifiable unless the animal is sufficiently valuable to isolate her for offspring or in hopes of recovery."

Tuberculous cows and the use of their milk in feeding calves, C. S. PHELPS (*Connecticut Storrs Sta. Rpt. 1897, pp. 243-251*).—The record for 2 years is given of 4 Devon cows which were condemned by the State Cattle Commission as tuberculous. At different times during the period the cows responded to the test and at other times they failed to respond. A statement of the veterinarian as to the present condition of the cows is given. Good care and treatment evidently prevented the development of the disease in these cases. Four calves from healthy cows were fed for periods of 5 to 16 months upon the milk of the 4 cows supposed to be tuberculous. The disease had not appeared in the udder of any of the cows. "In no instance do these calves show symptoms of the disease either by the tuberculin test or physical examinations."

Some diseases of animals caused by improper feeding, J. F. CONNOR (*Alabama Canebrake Sta. Rpt. 1897, pp. 13-15*).—The author discusses the symptoms and treatment of acute gastro-intestinal catarrh, colic due to overloading the stomach, and flatulent colic. The fact is emphasized that care should be taken not to overload the stomachs of horses and mules. They should not be fed immediately before starting on a long journey. Care should be taken not to feed moldy corn.

"Horses and mules should be fed 3 times a day and from separate mangers. The amount of food required by each animal can only be determined by observation by those in charge. Oats and corn mixed make a good food. This, with plenty of clean hay or fodder and an occasional bran mash (when there is a tendency to constipation) will keep the animal in good condition."

Relation of water supply to animal disease, A. W. BITTING (*Indiana Sta. Bul. 70, pp. 42-51, figs. 3*).—The amount of water which different animals consume is discussed.

"The diseases which arise as a result of supplying water in insufficient quantities, or not providing water in accessible places, are sporadic in character; that is, affect only an occasional animal or a few in a herd or flock. Probably the most serious disease having such cause is mad itch in cattle. This occurs especially in the fall of the year, when the cattle are upon dry pasture, or when turned in upon a dry stalk field. It may occur at other times, and also be due to other causes, but without doubt 90 per cent of the cases occurring in this State are directly traceable to this cause. Sheep also suffer from impaction and constipation, and large numbers die for want of proper water supply. Hogs, especially young ones, often succumb from like treatment. Horses probably suffer least loss, because they receive the greatest care in this respect, but no doubt many cases of colic, impaction, and constipation are traceable to this source."

The author notes that the dangers of diseases which arise from insufficient water are much less numerous than those due to supplying impure water. The possibility of infection with animal parasites and diseases conveyed by impure water is discussed at some length.

Blood serum in the prevention and treatment of infectious swine diseases, with a report of an experiment with swine plague antitoxin, V. A. MOORE (*Proc. Soc. Prom. Agr. Sci., 1897, pp. 26-34*).—Serum therapy in infectious swine diseases is discussed at some length.

In a test reported the presence of the disease in the herd was demonstrated by inoculation of rabbits. Eleven animals were treated. Of these 8 were sick when given the serum. Six died. Later 13 others were treated with injections of serum. Of these 8 were sick at the time of treatment and 5 died. Of the total number of animals treated, 11 died and 14 survived.

"It is difficult to draw further conclusions from this experiment or the results of others herein referred to. Just what the action on the animal body of the toxin injected is, by which it is converted into an antitoxin, has not as yet been satisfactorily explained. The investigations have not advanced sufficiently to enable us to say what species of animals will furnish the best antitoxin, but if it is to become practicable it seems that it must be one of the larger, such as the cow or horse. The question has also arisen, whether or not the method will be practicable even if the serum can be made efficient. To this a positive answer can not be given, but it seems highly probable that it can. It is easily administered, and the cost of its preparation ought not to preclude its use. It is suggested by the work on guinea pigs that the serum for hog cholera and swine plague can not be made interchangeable; neither can they be made a specific for dietary and filth diseases. These must be eliminated by the introduction of better sanitary methods. From the successes reported from serum therapy in other diseases it is reasonable to expect that eventually we may have antitoxins for the bacterial diseases of swine. Certainly the results of the experiment just described indicate that the investigations along these lines are more promising than any others which have been proposed for the discovery of a specific for swine plague."

Bacillus anthracis similis, J. MCFARLAND (*Centbl. Bakt. u. Par., 1. Abt., 24 (1898), No. 15-16, pp. 556, 557*).—A description is given of a bacillus cultivated from an abscess, the organism greatly resembling that causing anthrax.

On the production of Pasteur's vaccine for anthrax, J. MENDEZ (*Centbl. Bakt. u. Par., 1. Abt., 24 (1898), No. 17, pp. 616-619*).—Directions are given for the preparation and use of this vaccine.

Cattle tuberculosis: A practical guide for the farmer, butcher, and meat inspector, T. M. LEGGE and H. SESSIONS (*London: Baillière, Tindall & Cox, 1898, pp. 78, ill.*).

Acute pulmonary tuberculosis in the horse, H. THOMPSON (*Vet. Jour., 1898, July, pp. 21-23; noted in Centbl. Bakt. u. Par., 1. Abt., 24 (1898), No. 11, p. 430*).

The malignant foot disease of sheep, MARTENS (*Berlin. Klin. Wochenschr., 1898, No. 45, pp. 529-531*).

Foot and mouth disease in sheep and goats, HIMMELSTOSS (*Wochenschr. Tierheilk., 1898, No. 37, pp. 341-344; 38, pp. 349-353*).

Report of the commission appointed to investigate the hoof and mouth disease, LOEFFLER (*Centbl. Bakt. u. Par., 1. Abt., 24 (1898), No. 15-16, pp. 569-574*).—This is the fourth report of the commission of the Institute for Infectious Diseases at Berlin.

The sturdy, or staggers, of sheep, R. CASSIRER (*Arch. Path. Anat. u. Physiol. [Virchow], 153 (1898), No. 1, pp. 89-110*).—Pathological, anatomical, and bacteriological studies were made of this disease.

African hæmoglobinuric fever, commonly called black water fever, R. M. CONNOLLY (*British Med. Jour., 1898, No. 1969, pp. 882-885*).

Poisoning by Kafir corn (*Queensland Agr. Jour., 3 (1898), No. 4, p. 221*).—A note on this subject.

Powdered soap as a cause of death among swill-fed hogs, V. A. MOORE (*New York Cornell Sta. Rpt. 1898, pp. 409-418*).—A reprint of Bulletin 141 of the station (E. S. R., 9, p. 1090).

Systematic feeding and watering as a preventative of diseases in horses, J. B. PAIGE (*Agr. Massachusetts, 1897, pp. 254-267*).—A general discussion of the subject.

AGRICULTURAL ENGINEERING.

One year's work done by a 16-foot geared windmill, F. H. KING (*Wisconsin Sta. Bul. 68, pp. 41, figs. 13*).—The work done by a 16-foot geared steel power mill as well as the total wind movement, hour by hour, for the year ending March 6, 1898, are recorded in this bulletin. The mill is placed on the tower of the agricultural physics laboratory of the station and—

“Stands on a steel tower with its axis 22 ft. above the deck, 82 ft. above the ground outside the building, and about 106 ft. above lake Mendota. . . . The building is on the north slope of a hill, near its summit. It was impracticable to arrange the pumps and other machinery in the laboratory in such a way as to transmit the power directly to the driving shaft and an offset had to be made. . . . [This was done by means of] 14-inch flanged pulleys carrying a 6 inch rubber belt. . . . At the bottom of the 1-inch driving shaft a foot gear transmits the power to a 1½-inch horizontal shaft from which the pumps and other machinery are driven. . . . It will be observed that this arrangement has necessitated two transfers of power besides that in the head of the mill itself.”

The work of the mill was measured by pumping water from a reservoir having an area of 285 sq. ft. into a measuring tank holding 141.2 cu. ft.

“When the measuring tank was filled to the top of the siphon it was automatically emptied. By means of a float . . . arranged to work the pen on a chronograph, a record was secured of the number of times the tank was emptied each day and of the interval between each emptying. The mean height to which the water was lifted was, during March and April, 1897, 10.5 ft., but after that date the lift was increased to 12.85 ft.”

The pumps used were (1) a reciprocating pump with a 14-inch piston and a 9-inch stroke; (2) a bucket pump having a capacity of 120 gal. per minute, and (3) two pumps of the centrifugal type. Nearly all the work, however, was done with either the first or the second or the two combined. By combining the pumps in various ways it was possible to secure more work than by any one pump alone, but it was impossible to secure the maximum amount of work the mill was able to do.

“It frequently happened when the mill was left with one pump that during the night the wind became strong enough to carry two, but it did not get them until the next morning. So, too, when in the evening the wind was strong enough to work the two pumps and it was left with them the wind would go down until the two could not be handled, when if but one had been left this could have been worked all right. . . .

“The total amount of water pumped during the 365 days was 24,433 tanks, each holding 141.2 cu. ft. This is at the mean rate of 2.789 tanks each and every hour of the day, or 393.8 cu. ft. per hour and 6.562 cu. ft. per minute. Expressed in another way, the water pumped during the year is sufficient to cover 79.1 acres 12 in. deep or a rate of 2.6 acre-inches per day for the full year. . . . The largest amount of water pumped during any single day in the year was 39,510.2 cu. ft., which is a rate of 27.04 cu. ft. per minute.”

Calculating the work done to 10-day periods it was found that “the smallest amount of water lifted 10 ft. high in 10 days was enough to cover 9.87 acres 1 in. deep, and this occurred from July 28 to August 7,

at the time when water for irrigation is most needed. The largest amount pumped occurred during the 10 days from February 13 to 23, and was enough to cover 75.73 acres 1 in. deep."

"The mean amount of water pumped during the 100 days from May 29 to Sept. 6 was 24.549 acre-inches per 10 days, and as this is the season when the water is most needed in the United States it shows about what the capacity of such a plant is for irrigating purposes where the lift is 10 ft. With a lift of 20 ft. the capacity would be a little less than one-half of this amount. That is to say 10 in. of water can be given to 24.5 acres of ground during 100 days where the lift is 10 ft. and 12.25 acres where the lift is 20 ft.; and 20 in. of water could be given to one-half of these areas, respectively. There were, during the year, 5,239 hours when the velocity of the wind equaled or exceeded a mean of 9 miles per hour and there were 3,531 hours when the mean velocity did not reach 9 miles per hour, during which time there was no water pumped or but very little, because the wind was too light."

The mill worked on an average 14.32 hours per day during the whole year and 10.74 hours per day during the period from March 6 to September 1 (the irrigation season).

The horsepower of the mill was calculated from the amount of water pumped and determined by brake tests. The effective horsepower measured by the water lifted during the year (365 days of 24 hours each) was .1817. Figured on the basis of 14.32 hours per day, the effective horsepower was .3044.

"In the last trials [with brakes] the indicated horsepower was . . . 3.932 times the effective horsepower, and did this ratio hold true for all of the pumping the actual horsepower developed by the windmill would be $.3044 \times 3.932 = 1.197$ horsepower, while the curve of brake tests gave 2.107 horsepower."

Under similar conditions a $2\frac{1}{2}$ -horsepower gas engine lifted 2.35 times the water pumped by the mill. The indicated horsepower of the engine in these trials was 1.8, the effective horsepower 1.02.

"During a 6-hours' run with this engine there were lifted to a height of 12.85 ft. 13,202 cu. ft. of water, with a consumption of 458 cu. ft. of gas, costing \$1.25 per thousand. This is a cost for fuel of 95.4 cts. per day of 10 hours' work."

From tests of the mill in grinding corn when the wind velocity was from 9 to 30 miles per hour, it is calculated that—

"the total amount of feed which could be ground by the mill in a year was 871,500 lbs. or 15,560 bu. of 56 lbs. Grinding trials were also made with a Webster $2\frac{1}{2}$ -horsepower gas engine, and its rate was found to be 6,408 lbs. per day of 10 hours with a cost of fuel of 99 cts. The windmill was therefore able to do during the year the equivalent of 136 days of the 2.5-horsepower engine."

It was found that the loss of energy in the offset pulleys was .18 horsepower, and in the entire system of shafting, including the offset pulleys, .767 horsepower, when the shaft was making 500 revolutions per minute.

The sanitation of farm buildings, J. SCOTT (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 9 (1897), pp. 40-60, figs. 7.*)—The topics discussed are sanitary legislation, requirements for health, site and foundations, ventilation, lighting, drainage, conservancy, water supply, lambing folds, and disinfectants.

Lecture and articles on irrigation in India, America, Egypt, and Australia, R. WALLACE (*Edinburgh: Oliver & Boyd, 1898, pp. 31*).—Brief popular essays.

Unprofitable irrigation works, T. S. VAN DYKE (*Irrig. Age, 13 (1898), No. 2, pp. 45-50*).

Irrigation in Wyoming, J. SHOMAKER (*Irrig. Age, 13 (1898), No. 2, pp. 41-44*).

Irrigation of fields and lawns, R. V. (*Boly. Hort. et Agr., 10 (1898), No. 15, pp. 234-236, figs. 4; 16, pp. 253-255, figs. 3; 17, pp. 269, 270, figs. 5*).—A popular article describing a variety of methods and apparatus.

Mountain water courses as industrial aids (*U. S. Consular Rpts., 58 (1898), No. 219, p. 618*).—An abstract of a discussion of the desirability of building reservoirs to store storm waters in Germany.

Wide tires on farm wagons, J. M. STAHL (*Country Gent., 63 (1898), No. 2382, pp. 744, 745*).

Cow barn with framework of steel (*Irrig. Age, 13 (1898), No. 2, pp. 64-68, figs. 6*).

The experimental elevator at Berlin (*Deut. Landw. Presse, 25 (1898), No. 88, pp. 931, 932, figs. 2, plan 1*).—A description and the plan of the building are given and its purpose pointed out. Experiments in storing and handling grain under different conditions are to be conducted.

STATISTICS—MISCELLANEOUS.

Crop circular for October, 1898, J. HYDE (*U. S. Dept. Agr., Division of Statistics Crop Circ., Oct., pp. 8*).—This circular contains notes on the condition of the principal crops with estimates of the yields and a synopsis of the weather conditions east of the Rocky Mountains for September, 1898. The English, French, and Hungarian estimates of the world's wheat crops by countries for 1897-98; the rainfall percentages east of the Rocky Mountains from April to September, and the average yield per acre and average condition of crops by States and Territories October 1, 1898, are given in tables.

Crop circular for November, 1898, J. HYDE (*U. S. Dept. Agr., Division of Statistics Crop Circ., Nov., pp. 4*).—Preliminary estimates on the crops of 1898, and on the wheat crop of a number of foreign countries are given.

Report on crops, live stock, etc., in Manitoba (*Ontario Dept. Agr. and Immigr. Bul. 56, pp. 25*).—This bulletin is a summary of the conditions of the crops and live stock, estimates of the yield of various crops, and the quantities of land broken during the season. General notes on the agricultural conditions of the several districts are given.

Twelfth Annual Report of Alabama Canebrake Station, 1897 (*Alabama Canebrake Sta. Rpt. 1897, pp. 15*).—Contains a financial statement for the civil year ending December 31, 1897, and a report on station work, noted elsewhere.

Tenth Annual Report of Connecticut Storrs Station, 1897 (*Connecticut Storrs Sta. Rpt. 1897, pp. 276*).—This includes general remarks on the work of the station during the year; a financial report for the fiscal year ending June 30, 1897; various articles on foods and animal production, abstracted elsewhere; and an index to annual reports 1 to 10, inclusive.

Report of Massachusetts Hatch Station, 1897 (*Massachusetts Hatch Sta. Rpt. 1897, pp. 138*).—This contains a brief summary of station work and a financial statement for the fiscal year ending June 30, 1897, and reports of the various departments, noted elsewhere.

Eleventh Annual Report of New York Cornell Station, 1898 (*New York Cornell Sta. Rpt. 1898, pp. XIX: Append. I, pp. 337-721; II, pp. XI; III, pp. 69-125*).—This contains reports by the director, treasurer, chemist, botanist, entomologist, agriculturist, horticulturist, veterinarian, and the assistant professor of dairy husbandry and animal industry for the year ending June 30, 1898. Appendix I is made up of reprints of Bulletins 138-149 of the station. Appendix II gives a detailed state-

ment of receipts and expenditures of the station for the fiscal year ending June 30, 1898. Appendix III consists of reprints of Teacher's Leaflets on Nature Study 8-11.

Reports of North Carolina Station for 1897 and 1898 (half year) (*North Carolina Sta. Rpt. 1897 and 1898, pp. XLIV+423-426*).—This contains reports of the director and heads of departments covering the work of the station from January 1, 1897, to June 30, 1898, and financial statements for the fiscal years ending June 30, 1897 and 1898.

The North Carolina Agricultural Experiment Station, W. A. WITHERS (*North Carolina Sta. Spec. Bul. 48, pp. 11*).—Notes on the station staff and the equipment and work of the station.

The station and its exhibit (*North Carolina Sta. Spec. Bul. 50, pp. 16*).—A special bulletin explanatory of the station and its exhibit at the annual fair of the North Carolina Agricultural Society in 1898.

Experiment Station Work, VII (*U. S. Dept. Agr., Farmers' Bul. 84, pp. 32, figs. 8*).—This includes the following popular articles: Home-mixed fertilizers, forcing asparagus in the field, field selection of seed, potatoes as food for man, corn stover as a feeding stuff, feeding value of sugar beets, salt-marsh hay, forage crops for pigs, ground grain for chicks, skim milk for young chickens, by-products of the dairy, stripper butter, curd test in cheese making, and gape disease of chickens.

The development of agriculture in Japan (*L'Engrais, 13 (1898), No 47, pp. 1117, 1118*).

Fourth report of progress on extension work, I. P. ROBERTS (*New York Cornell Sta. Rpt. 1898, pp. 633-654, maps 3*).—A reprint of Bulletin 146 of the station (*E. S. R.*, 10, p. 498).

NOTES.

ARIZONA STATION.—A new office building, costing \$340, has been erected at the substation at Phenix. Attention is being given to the introduction of plants not indigenous to that section, the testing of new varieties of fruits, and especially the date palm, which promises success. The growing and fattening of live stock has been taken up. The result of sugar-beet experiments indicates that beets of high quality may be grown far south of the usually accepted region for first-class beets. Inoculation experiments have been made with the crown knot of fruit trees, showing its ability to spread by this means.

MONTANA COLLEGE AND STATION.—E. V. Wilcox has resigned his position as zoologist and entomologist in the college and station, to take effect April 1, 1899, and has accepted a position in the Office of Experiment Stations of this Department, *vice* F. C. Kenyon, resigned. Dr. Wilcox will have charge of the departments of zoology, entomology, and veterinary science of the Experiment Station Record. John M. Robinson and Walter S. Hartman, both of Bozeman, have been appointed on the executive board, *vice* Nelson Story and Walter Cooper, whose terms have expired.

NEW MEXICO COLLEGE AND STATION.—C. A. Keffer, of the Division of Forestry of this Department, has been appointed agriculturist and horticulturist in the college and station. He will enter upon his new duties in the early spring.

PENNSYLVANIA COLLEGE AND STATION.—G. E. Voorhees, formerly superintendent of the National Farm School of Doylestown, Pennsylvania, has been employed as temporary instructor in agricultural chemistry during the absence of Prof. William Frear at the farmers' institutes. Much interest is being manifested at various farmers' institutes in the work of the station and school of agriculture, and numerous applications for reports and bulletins are constantly being received.

SOUTH CAROLINA STATION.—The board of trustees at a recent meeting ordered the college farm divorced from the experiment station. A short bulletin has just been prepared for the purpose of encouraging cooperative experimental work among the farmers, especially among the auxiliary experiment clubs organized under the auspices of the farmers' institutes last summer.

MISCELLANEOUS.—Memorial services for the late Senator Justin S. Morrill were held in both branches of Congress February 22. Several addresses were delivered, which, together with the report of the funeral services held in the Senate Chamber and at Montpelier, Vt., are published in the Congressional Record for that date. The executive committee of the Association of American Agricultural Colleges and Experiment Stations, at a recent meeting held in Washington, voted to recommend that all land-grant colleges observe April 14, next, Senator Morrill's birthday, with appropriate services in his honor. They also voted to invite President Buckham, of the University of Vermont, to prepare a set of resolutions to be presented at the next convention of the association, and President Atherton, of Pennsylvania State College, to present an address on Senator Morrill's life work in the interests of the education of the industrial classes.

Dr. C. G. Gibelli, professor of botany and director of the Botanic Institute of the University of Turin, died September 16, 1898.

Dr. van Tieghem, the well-known botanist, has been elected president of the Paris Academy of Sciences.

Dr. W. Schimper, of Bonn, has accepted a call to Basel as professor and director of the botanical garden.

Dr. F. W. C. Areschoug, professor of botany of the University of Lund, has retired and Prof. S. Berggren has been chosen as his successor.

Dr. A. Zschokke has been chosen director of the recently established Wine and Fruit Culture School at Neustadt, Bavaria.

Dr. Adolph Osterwalder has become assistant in the laboratory of plant physiology of the Experiment Station and School for Fruit, Wine, and Garden Culture in Wädenswil, Switzerland.

Dr. Roux, of the Pasteur Institute, has been elected a member of the agricultural section of the Paris Academy of Sciences, taking the place left vacant at the death of Aimé Girard.

At a recent meeting held in London to consider questions connected with Cambridge University it was stated that the Drapers' Company would subscribe \$4,000 a year for ten years in support of a professor of agriculture. Sir Walter Gilby has subscribed \$1,000 a year for the same period to provide for a readership of agriculture.

The commission which was appointed sometime ago in France to consider the question of colonial botanical gardens and agricultural experiment stations has recommended that a station be established in each of the French colonies and a central station for the distribution of seeds and plants. A decree has been issued organizing such a station at Vincennes, and J. Dybowski has been appointed director.

Notice has been received that the International Veterinary Congress will be held at Baden, Germany, August 4-14, 1899. The subjects to be discussed include prophylactic measures to prevent the spread of cattle diseases by the export of animals, treatment of tuberculosis in domestic animals, use of flesh and milk of animals affected by tuberculosis, and requirements for inspection of meat, cure of foot and mouth disease and diseases of swine, dissemination of veterinary instruction, preparation of a uniform anatomical nomenclature in veterinary medicine, and cure of rabies.

The new bacteriological institute of the University of Louvain, of which Professor Denys is the head, was formally opened in February. A special department of the institute will be devoted to the preparation of therapeutic serums, etc.

The December number of the *Forstlich-naturwissenschaftliche Zeitschrift* announces the discontinuation of that journal owing to the removal of the editor, Dr. Carl Freiherr von Tubeuf, from Munich to Berlin, as previously noted (E. S. R., 10, p. 400).

CONTENTS OF Vol. X, No. 8.

	Page.
Editorial notes: Agricultural experiment station in Alaska	701
Twelfth annual convention of the Association of American Agricultural Col- leges and Experiment Stations, W. H. Beal	704
Recent work in agricultural science	714
Notes	799

SUBJECT LIST OF ABSTRACTS.

CHEMISTRY.

The determination of citrate-soluble phosphoric acid in Thomas meal, J. Freundlich	714
Reynoso's method of analysis of phosphates. U. Anthony and G. H. Mondolfo. A study upon the phosphoric acid dissolved in the soil solutions, T. Schloes- ing, jr	714
Determining the density of sugar cane, A. A. Ramsay	715
The proteids of cream, E. F. Ladd	715
Report of the chemist, E. Fulmer	716

BOTANY.

Economic grasses, F. Lamson-Scribner	718
A report upon the forage plants and forage resources of the Gulf States, S. M. Tracy	718
The Red Desert of Wyoming and its forage resources, A. Nelson	718

	Page.
On the rôle of the awns of Gramineæ, N. I. Vasilyev	718
On the vegetative period of plants, L. P. Nilssen	719
A study of the roots of perennial plants, E. S. Goff	720
Evaporation and plant transpiration, W. Maxwell	721
The fertilization of cultivated legumes, C. Fruwirth	722
Alinit, Gerlach	722
Experiments with Nitragin, E. Wollny	722
On the assimilability of organic nitrogen in sterilized media, A. Lyebedyev	723
The geographical distribution of cereals in North America, C. S. Plumb	723
Life zones and crop zones of the United States, C. H. Merriam	724

ZOOLOGY.

Cuckoos and shrikes in their relation to agriculture	726
The winter food of the chickadee, C. M. Weed	726
Feeding habits of the chipping sparrow, C. M. Weed	726
Joint report of the botanist and entomologist and the veterinarian on spermophile or ground-squirrel investigations, C. V. Piper and S. B. Nelson	727

AIR—WATER—SOILS.

Percolation, storage, and movement of water in the soil, P. P. Dehérain	727
Percentage of water retained by long columns of sand, F. H. King	727
The farm water supply, F. W. Morse	730
The treatment of swamp or humus soils, F. H. King	728
Fertilizer experiments with Indian corn on marsh soils, F. W. Woll	729
Pot-culture tests of the productiveness of the soils of Minong pine barrens in Douglas County, Wisconsin, F. H. King	730

FERTILIZERS.

On the spreading and plowing under of barnyard manure, P. P. Dehérain	731
The fertilizer control for 1897, W. A. Withers	732
Fertilizer inspection, C. D. Woods	734
Commercial fertilizers, M. A. Seovell, A. M. Peter, and H. E. Curtis	734
Fertilizer analyses, R. C. Kedzie	734
Analyses of commercial fertilizers, H. J. Wheeler and B. L. Hartwell	734
Analysis of licensed commercial fertilizers, F. W. Woll	735
Experiments on the action of phosphoric acid in bone meal and Valserine phosphate as compared with that of superphosphate and Thomas slag, P. Liechti	733
Lime, nitrogen, and soda, H. J. Wheeler	735

FIELD CROPS.

Report of the department of agriculture of Washington Station	735
Reports of the department of agriculture and horticulture, F. A. Huntley	749
Fiber flax investigations, F. A. Huntley	736
A report on the culture of hemp in Europe	737
The influence of soil moisture and fertility on the development of the oat plant, M. Tucker and C. von Seelhorst	737
Experiments with oats, J. F. Duggar	738
The influence of depth of planting on the growth and productiveness of potatoes, E. S. Goff	740
Growing rye after potatoes, M. Fischer	740
The growth and use of the rape crop, J. A. Craig	741
Special report on the beet-sugar industry in the United States, 1897	741

	Page.
A soil study of sugar beets, W. P. Headden	743
New Mexico sugar beets, 1897, A. Goss	715
The importance of the right amount and the right distribution of water in crop production, F. H. King	746

HORTICULTURE.

A comparison of the "Station" tomato with three standard varieties, E. S. Goff.	751
On the structure of the epidermal layer, and the cause of the varying keeping qualities of pomaceous fruits, A. Zschokke	751
The application of artificial root pressure to recently transplanted trees, E. S. Goff	751
Orchard cultivation, T. J. Burrill and J. C. Blair	752
The green gage group of plums, F. A. Waugh	753
The composition of fresh fruits, A. Girard	754
The protection of orange groves against frosts	751
The degree of cold endurable by flower buds of the plum and cherry, E. S. Goff.	755
Small fruits, E. S. Goff	757
Is the ripening season of a pistillate strawberry affected by the blooming period of its pollenizer? E. S. Goff	755
Cold <i>vs.</i> warm water for greenhouse plants, F. Cranefield	755
Notes on watering, F. Cranefield	756

SEEDS—WEEDS.

The influence of varying amounts of water on the germination of beet seed, E. S. Goff	759
Resistance of seed to immersion in water, H. Coupin	759
The Russian thistle in Washington, C. V. Piper	760
Twelve of Idaho's worst weeds, L. F. Henderson	760
Report of botanist and entomologist, C. V. Piper	760

DISEASES OF PLANTS.

Diseases of plants, A. P. Anderson	763
Potato diseases, E. Roze	761
Diseased potatoes, G. Abbey	761
The effect of various copper preparations on the potato, R. Thiele	762
Report of the department of botany, L. H. Henderson	763
A new copper fungicide for combating black rot, J. Perrand	762
A trial of "Ceres pulver" for the prevention of smut in oats, E. S. Goff	762

ENTOMOLOGY.

On the poison of honeybees, J. Langer	765
Report of the department of entomology, J. M. Aldrich	765
Some insects of the year 1897, W. P. Barrows and R. H. Pettit	766
Colorado's worst insect pests and their remedies, C. P. Gillette	770
On the biology and taxonomy of some species of mining Diptera, W. C. Brashnikov	766
A new squash bug, F. H. Chittenden	767
Scale insects, C. E. Chambliss	767
A new danger to fruit growers, L. R. Taft	771
Summer treatment for the San José scale, W. B. Alwood	771
Legislation for the suppression of the San José scale, W. B. Alwood	771
The life history of <i>Schizoneura lanigera</i> , W. B. Alwood	768
The proposed attempt to introduce <i>Blastophaga psenes</i> into California, L. O. Howard	768

FOODS—ANIMAL PRODUCTION.

EXPERIMENT STATION RECORD.

VOL. X.

No. 8.

To the list of agricultural experiment stations in this country must now be added that of Alaska, which has been organized under the supervision of this Department. For the past two years the agricultural conditions and possibilities of that country have been inquired into with a view to determining what encouragement there might be for undertaking experiment station work. The first year Congress appropriated \$5,000 for this inquiry, and the result was so encouraging that last year the appropriation was increased to \$10,000. Prof. C. C. Georgeson, until recently connected with the Kansas Agricultural College and Experiment Station as agriculturist, was placed in charge of the work. The Weather Bureau of this Department cooperated in the enterprise by establishing a special meteorological service for Alaska. Headquarters were established at Sitka, a small building being rented for office purposes. Several small patches of cleared land at Sitka, including the garden of the Governor of the Territory, were secured, and on these were planted seeds of a large number of cereals, forage plants, and vegetables, specially selected for the purpose. More restricted experiments in growing cereals and vegetables were made at Skagway by a settler in that place who was formerly connected with the Kansas Agricultural College.

The results at Sitka brought out some interesting facts regarding the soil and the suitability of the climate for growing food crops. It was demonstrated that oats and barley will not only make an excellent growth, but will mature in southeastern Alaska. This has not been determined for wheat and rye, but experiments with fall-seeded grain are now in progress. The Riga flax grew excellently, and gave promise that a good commercial article can be produced, suggesting a possible industry for the natives. Several kinds of clovers "grew with remarkable vigor," the plants from the American seed making the best growth. Buckwheat made a good growth and bloomed abundantly, but was killed by frost before it was ripe, owing to late planting. Among the vegetables, asparagus, beets, carrots, cress, kale, kohlrabi, lettuce, onions, parsnips, peas, potatoes, radishes, ruta-bagas, rhubarb, salsify, turnips, and Windsor beans all did well on old ground, and showed that the climate and soil were favorable to their growth. Cabbage and cauliflower suffered from club root, but the plants which escaped indicated that these vegetables can be grown with proper treatment.

At Skagway the land was newly cleared and was "raw and sour, containing a large percentage of imperfectly decayed vegetable matter, mostly the rotten wood of conifers which had accumulated in the course of ages." But in spite of these unfavorable conditions and the fact that planting was delayed until June, oats, barley, and flax were successfully grown, together with a long list of vegetables.

One important fact developed during the past season is the sensitiveness of certain varieties and crops to the new ground, and its possible explanation of the adverse criticisms which have been made on Alaska as a farming country. The newly broken ground is raw, sour, and water-logged, and contains a large amount of decaying wood, etc. It needs to be aerated, drained, and in many cases limed to make it suitable for most cultivated plants. For example, barley and flax were nearly total failures on new ground and oats were only a partial success, while on old ground they all made excellent growth. The same was true of varieties of clover from Norway, and a considerable number of vegetables. The seed in all cases germinated promptly in the new ground, but the young plants languished, turned yellow, and soon died. The failure in all these cases was due to the soil and not to the climate.

In addition to these field trials, observations and records were made of soil temperatures, and samples of soil were taken for moisture and other determinations. A number of places in the coast region of Alaska were visited, and surveys and reservations of land for experimental purposes were made at Sitka, Kadiak Island, and Kenai in Cook Inlet. Considerable additional information relative to the agricultural conditions in different parts of Alaska was obtained in response to circulars of inquiry.

Dr. Walter H. Evans, of this Office, continued his botanical survey during the past summer, adding a considerable number of new specimens of the flora of the coast region. Several species were found which give promise of considerable value as sand binders. The reports of Professor Georgeson and Dr. Evans for the past year have recently been issued.

On the whole, the outcome of the two years' investigation was sufficiently encouraging to recommend the establishment of a station or stations on a definite basis, and Congress has accordingly increased the appropriation for the ensuing year.

The main station will be located at Sitka, and an office and laboratory building costing about \$5,000 will be erected there this spring on a small tract of land reserved for that purpose. Other land near Sitka will be cleared and broken and put in shape for field trials. This will be of little use the coming season except for growing forage for the work animals, but several small patches of old ground have been secured for continuing the field tests.

At Kenai a tract of land will be cleared and broken, and log silos will be erected for ensiling the native grass, which is abundant and nutritious, but not easily made into hay on account of the very frequent

rains and high humidity. Hardly more than a beginning can be made at that place during this season. Arrangements have been made with a resident of Kadiak to begin experiments on old ground at that place; and cooperative trials will be made at various other places, so that a quite extensive area of country will be included in the work this year.

The headquarters of the Weather Bureau will be moved into the interior, but it will continue to cooperate with the Alaska station, and will make observations on soil temperatures at different places.

Professor Georgeson will remain in charge of the work, and will reach Alaska about the middle of April. He will take with him Mr. C. H. Robison, a graduate of the Michigan Agricultural College in 1895, as assistant at Sitka, and Mr. H. P. Nielsen, formerly of the Kansas Agricultural College, as assistant at Kenai for the summer. He has also engaged three laborers to go to Alaska for the summer, as there is difficulty in procuring satisfactory farm laborers there. Several yoke of oxen will be shipped there from Oregon, and a full line of implements, including wagons, stump pullers, plows, cultivators, harrows, hand tools, etc., will be taken.

The new station will not be on the same basis as the stations receiving the Hatch fund. It will be maintained by funds appropriated for the Secretary of Agriculture and not subject to the provisions of the Hatch Act. It will be conducted under the supervision of this Office, as the Alaska investigations of the past two years have been, and reports of its operations will be made to Congress annually. Moreover, its problems will be different from those presented to stations in States where agriculture is already a reality. There can not be said to be any agriculture in that vast tract of country at present. Aside from the products of small gardens and the fishing industry, the country is almost entirely dependent for its food supplies on materials shipped there. An important function of the station will be to prepare the way for agriculture and to aid in its development. It will be necessary to demonstrate the capabilities of different sections of the country, determine the best methods of managing the soil, procure varieties of plants suited to the climate and the season, devise methods for preserving forage crops, etc.

Much interest in the establishment of a station has developed among people who have gone to Alaska during the past few years. It has become apparent to them that if the mineral wealth of the Territory is to be developed, sufficient agriculture should be developed, if possible, to furnish at least a part of the food products required by the increasing population, thus reducing the cost and furnishing a greater diversity of industries. If it can be shown that it is possible for a man to live there on the product of the land, without being entirely dependent on the mines, a strong factor will have been gained for the development of the country. If the home markets can be supplied with the principal food products, the independence of this isolated country will be materially increased and it will become a far more attractive place in which to live.

TWELFTH ANNUAL CONVENTION OF THE ASSOCIATION OF AMERICAN AGRICULTURAL COLLEGES AND EXPERIMENT STATIONS.

W. H. BEAL,

Office of Experiment Stations.

The twelfth annual convention of the Association of American Agricultural Colleges and Experiment Stations was held at Washington, D. C., November 15-17, 1898. All sections of the country were represented, there being 154 delegates and visitors in attendance. Arizona, Kansas, Oregon, and Texas were the only States which did not send delegates.

GENERAL SESSIONS.

The convention was called to order and presided over by the president of the Association, H. C. White.

A report of the executive committee, briefly reviewing the work of that committee during the past year, was submitted by the chairman, H. H. Goodell.

The usual section reports were submitted by the chairmen of sections, as follows: College work, Alston Ellis; agriculture and chemistry, R. J. Redding; horticulture and botany, S. T. Maynard; and entomology, J. B. Smith. No report was received from the section on mechanic arts.

The address of the president, H. C. White, was a scholarly presentation of the purposes and potentialities of the Association, showing the breadth and strength of the scientific and industrial education offered by the land-grant colleges, and pointing out how such institutions may be made to produce the "scholar" just as truly as schools built on classical foundations.

"The industries whose fruits satisfy the material needs of man which, if you please, accumulate his wealth, which regulate his commerce and direct his trade, are no longer exclusively or best served by the unremitting muscular energy of toiling millions, nor yet by high efficiency of manual skill. They have come to involve in their prosecution intellectual abilities of the highest order and become not only thereby fit occupation in activity for him who is to be the scholar but, indeed, unremunerative and unadapted to those lacking some part of scholarly training. . . . The intellectual training which shall best serve the application of intellectual power to industrial pursuits is not yet systematized, has not yet been given a satisfactory form to serve for pedagogic purposes. To give it such form, to fit it to the needs and the uses of the great masses of those who, in the nature of things,

may not have other scholarly attributes than that of action and at the same time suit it to the equipment of the scholar who shall be differentiated from the masses is one high and important office of the American university which is to be."

He pointed out that the land-grant colleges which derive their support so largely from the United States Treasury together constitute this great national university.

On motion of G. W. Atherton, the president's address was referred to a committee of five for consideration. This committee, which consisted of G. W. Atherton, J. E. Stubbs, R. H. Jesse, E. A. Bryan, and J. K. Patterson, subsequently reported as follows:

"(1) That the proceeds of the United States land-grant act of 1862 and the annual appropriations provided for by the acts of Congress of 1887 and 1890 are a national trust to be administered by the several States in strict accordance with the letter and the spirit of the grant.

"(2) That the land-grant colleges whether organized separately or as branches of State universities are primarily educational institutions required by law to teach certain branches of learning.

"(3) That these branches of learning are to be taught with special reference to their 'applications in the industries of life.'

"(4) That this requirement involves a thorough fundamental training in the principles of the mathematical, physical, and natural sciences, in order that their practical applications may be clearly understood, and forbids that the institutions shall in any way be regarded as 'trade schools.'

"(5) That the land-grant colleges are required by law to provide a 'liberal' as well as a 'practical' education, and that it is therefore their special duty to study, practice, and develop sound principles of instruction in the teaching of all branches of learning both liberal and technical, to the end that the subjects taught may be made the means and instruments of a true education, as well as a means of acquiring a body of concrete knowledge.

"(6) That the aim of all research should be to learn the truth, and the aim of all teaching to teach the truth and nothing but the truth; and that to this end freedom of research and freedom of teaching are indispensable.

"(7) That all teaching should accordingly be absolutely free from partisan or sectarian bias; that the institutions should be free from partisan or sectarian control, and that no interference in the administration or in the teaching or in the tenure of office should be allowed on partisan or sectarian grounds."

The Secretary of Agriculture responded to an invitation to address the convention. He referred to his efforts to bring the Department of Agriculture into closer sympathy with the agricultural colleges and experiment stations, and briefly discussed the character and extent of the work done by the Department in the interest of agriculture. He urged upon the agricultural colleges the importance of special effort to make their courses attractive to farmers' sons and especially adapted to their needs. He suggested as means to this end the introduction of nature studies into the common schools, and the more thorough training of teachers for such schools in the natural sciences.

A resolution, introduced by R. H. Jesse, favoring the introduction into the public and grammar schools of nature study and instruction in the elements of the economic sciences, and the training of teachers in these various lines at the agricultural colleges, was adopted.

A report of the committee on graduate study at Washington,¹ submitted through G. E. MacLean, introduced a discussion of one of the most important topics taken up by the convention. The report gave a detailed account of the operations of the committee during the past year, with the conclusions that—

“It is entirely practicable to provide for the use of the Library of Congress and the collections of the Smithsonian Institution, the National Museum, and of the various scientific and other bureaus in the several departments of the General Government, by graduate students of the land-grant and other colleges for study and research, and that it is also practicable to organize, coordinate, and direct such work so as to make it eminently effective. . . .

“It submits tentatively that Congress might be asked to provide for the establishment of an administrative office in Washington, preferably in the Smithsonian Institution, in which graduate students of the institutions we represent, and others as well, might be enrolled and directed to the appropriate departments.

“To maintain this office, pay the expenses of administration, support graduate courses of research, freely open to the graduate students of the land-grant and other colleges without distinction of race, sex, or color, on such terms as the administrative office should prescribe, and to aid such students in their researches, Congress might be asked to make an appropriation of, say, \$25,000, to be increased annually \$1,000, to be expended under the discretion of the institution or department in which the office of administration may be located.”

The discussion of this subject was participated in, upon invitation of the chairman, by Mrs. Calvin S. Brice and ex-Governor J. W. Hoyt, who spoke of their interest in the subject and of the efforts of the George Washington Memorial Association to establish a National University in Washington.

The report was approved and adopted. The committee was continued and empowered, in connection with the executive committee, to propose and secure if practicable such legislation as will carry out the object and purposes of the resolution under which it was appointed. The committee consists of C. Northrop (chairman), Alston Ellis, M. H. Buckham, G. E. MacLean, Alexis Cope, and J. H. Washburn.

Another subject which provoked lively discussion was the detail of military officers to the agricultural colleges. Much dissatisfaction was expressed with the present condition of affairs in this respect. The matter was finally “referred to the executive committee with power.”

A paper on Land-grant and other colleges and the national defense² was read by C. W. Dabney. In this paper it was urged that the Government take steps to recognize these institutions more fully as agencies for the training of the officers who will be needed for our increased military establishment. A considerable number of the graduates of these institutions served with distinction in the war just closed, and there is good reason to believe that in the reorganization of our volunteer army it will be necessary to look to these institutions very largely for the trained material needed to put the volunteer army on a more efficient basis.

¹ U. S. Dept. Agr., Office of Experiment Stations Bul. 49, p. 39.

² This paper has been published as Circular 40 of the Office of Experiment Stations.

On motion of A. W. Harris, a committee of seven, consisting of G. W. Atherton (chairman), A. W. Harris, C. W. Dabney, A. Cope, H. H. Goodell, R. H. Jesse, and H. C. White, was appointed "to consider the organization and extent of military work which can be properly undertaken by the land-grant colleges and the proper relation of this work to the military service of the several States and of the United States; that this committee, in conjunction with the executive committee of the Association, be empowered to propose and secure if practicable such legislation as may be necessary to carry out the conclusions which the committee may reach."

One of the important reports submitted was that of the committee on the collective station exhibit at the Paris Exposition. This report gave the general features of a plan which the committee has formulated for this exhibit, which is to be similar to that at the World's Fair at Chicago. The recommendation of the committee that the exhibit when prepared should be a permanent one and that the Secretary of Agriculture be requested to provide a proper place for it after its return from Paris, was adopted by the Association. The committee was continued and instructed to prepare the exhibit. This committee is made up as follows: H. P. Armsby (chairman), W. H. Jordan, A. W. Harris, M. A. Scovell, and A. C. True.

As was expected, the question of amendment to the constitution, brought over from the previous convention,¹ received very full consideration and discussion. The discussion developed a very strong opposition to confining the work of the Association to purely administrative matters. The majority report recommending the abolition of all sections was rejected, while the minority report providing for 3 sections, (1) administrative, (2) agriculture, and (3) horticulture, was laid on the table.

The committee on engineering experiment stations submitted a brief report of progress, and recommended that the bill which has been drawn up to be laid before Congress be so amended as to permit investigation in marine engineering, naval architecture, and the theory and use of projectiles on land and sea. The committee, consisting of C. S. Murkland (chairman), F. P. Anderson, M. H. Buckham, A. W. Harris, and J. E. Stubbs, was continued, and directed to cooperate with the executive committee in urging this legislation upon Congress.

The report of the bibliographer, A. C. True, outlined the bibliographical work of the Department of Agriculture during the year, and gave a list of 10 or more bibliographies of interest to agriculture which have recently appeared.

The committee on indexing agricultural literature submitted through the chairman, A. C. True, a report embodying a scheme of classification of agricultural literature prepared by W. P. Cutter, Librarian of the Department of Agriculture. "This classification is designed to cover agriculture only, and not such subjects as farm architecture, systematic

¹U. S. Dept. Agr., Office of Experiment Stations Bul. 49, p. 28.

entomology and botany, or farm engineering. The scheme is designed to be used with the Dewey system of classification."

A. C. True submitted the third report of the committee on methods of teaching agriculture.¹ This gives a syllabus for a course of instruction in agronomy (plant production). After some discussion, it was voted that the reports of this committee be made the subject of special consideration at the next annual convention.

A paper by O. L. Waller entitled What shall be the character of the preparatory work required to enter four-year engineering degree courses? was reported from the section on mechanic arts and read in general session.

A paper from the section on agriculture and chemistry entitled Some notes in connection with the testing of cows as to milk and butter production by M. A. Scovell was read in general session.

T. E. Miller, president of the Colored Normal, Industrial, Agricultural, and Mechanical College of South Carolina, read a paper on The undeveloped agricultural resources of South Carolina.

The subject of mailing lists for experiment stations was discussed, and a resolution was adopted urging upon all stations the use of the mailing lists prepared by the Office of Experiment Stations.

C. C. Georgeson and A. C. True spoke briefly of the progress made in investigating the agricultural possibilities of Alaska, a number of products grown there during the season of 1898 being exhibited.

During the course of the convention the Association as a body paid its respects to the President of the United States.

Invitations were extended to the Association to hold its next convention in California, Washington, and New York. The matter was referred to the executive committee.

Officers were elected for the ensuing year as follows:

President, H. P. Armsby, of Pennsylvania; vice-presidents, J. E. Stubbs of Nevada, C. S. Murkland of New Hampshire, J. L. Snyder of Michigan, P. H. Mell of Alabama, and F. P. Anderson of Kentucky; secretary and treasurer, E. B. Voorhees, of New Jersey; executive committee, H. H. Goodell of Massachusetts (chairman), A. Cope of Ohio, J. H. Washburn of Rhode Island, W. M. Liggett of Minnesota, and *ex officio* the president, the junior ex-president (H. C. White), and the secretary and treasurer; bibliographer, A. C. True, of Washington, D. C.

Section on college work.—Chairman, C. W. Dabney, of Tennessee; secretary, C. E. Coates, of Louisiana.

Section on agriculture and chemistry.—Chairman, J. L. Hills, of Vermont; vice-chairman, C. E. Thorne, of Ohio; secretary, E. Davenport, of Illinois.

Section on horticulture and botany.—Chairman, L. H. Pammel, of Iowa; secretary, S. B. Green, of Minnesota.

¹ U. S. Dept. Agr., Office of Experiment Stations Circ. 39.

Section on entomology.—Chairman, C. W. Woodworth, of California; secretary, L. Bruner, of Nebraska.

Section on mechanic arts.—Chairman, C. S. Murkland, of New Hampshire; vice-chairman, G. A. Harter, of Delaware; secretary, F. P. Anderson, of Kentucky.

MEETINGS OF SECTIONS.

SECTION ON COLLEGE WORK.

The sessions of the section on college work were devoted to papers and discussions on recent changes in the theory of higher education and the relation of the churches to State colleges and universities.

Discussion of the first subject was introduced by a paper presented by E. A. Bryan, who traced the progress of several American colleges in their attempts to improve their curricula by giving to the natural and physical sciences an equal place with linguistic and philosophic subjects. The nature of education will be determined by the use to which it is to be put, and the modern idea that the purposes of higher education include the application of its results to industry and the material welfare of mankind has done much to revolutionize the college methods. The separation of culture and utilitarian ends was considered impossible.

R. W. Silvester spoke of the impulse given by President Eliot to higher education by the introduction of the elective system into the undergraduate courses. The evolution of the individual and the changed attitude of instructor to student were dwelt upon. The Association was urged to aid in the establishment of a national university in Washington characterized by the truly scientific spirit.

J. E. Stubbs gave an historical retrospect of national civilizations by which education in its modern aspect is to be interpreted. He said the end of education should be the development of cultured manhood which fits for a passport to high position in every sphere of usefulness.

A. W. Harris read a paper on The relation of the church to State colleges and universities, in which he urged the obligation of the churches to extend their care to students in undenominational as well as denominational institutions, and suggested the establishment by the different denominations of dormitories and chapels for the students of their membership. It was also suggested that the churches might furnish funds to provide the State colleges and universities with preachers and lecturers that theological courses might be maintained.

In the discussion which followed, J. L. Snyder expressed the opinion that the churches did not have the means to carry out the plans suggested by Dr. Harris in addition to keeping up denominational schools. The most effective way for the churches to hold their young people was to place in the pulpits of the university towns and cities the stronger preachers in their denomination. The faculty should encourage the students to activity in the churches in the immediate vicinity.

M. H. Buckham, J. H. Canfield, and W. I. Chamberlain agreed with the previous speaker that religious instruction might be safely left to the church and the home. The subject was further discussed by A. B. Peebles and J. E. Stubbs, the latter holding that the State colleges in the far West in nonchurch going localities needed the influence of the church, and that the different denominations should plant church organizations and auxiliary colleges in the vicinity of such institutions and enable the students to have direct religious culture under the direction of their own church.

SECTION ON AGRICULTURE AND CHEMISTRY.

In the section on agriculture and chemistry the first paper was submitted by W. I. Chamberlain. The subject of this paper was Recent investigations, together with former experiments, on the relation both of commercial fertilizers and of clover to wheat growing in Ohio.¹ In it the author quotes statistics which he believes tend to show that there has been a relative decline in clover growing and an increase in the acreage and yield of wheat in Ohio. This increased production of wheat he believes to be due largely to a more liberal use of commercial fertilizers. The direct purchase of unmixed fertilizing materials for cash at wholesale is considered impracticable as a rule, although sound in theory. He stated that in his opinion the attitude of some of the experiment stations has seemed to be antagonistic to fertilizers, and that he deplored this state of affairs.

This paper provoked a lively discussion of the relation of the experiment stations to the fertilizer business. W. Frear maintained that in those States where the purchase of fertilizers is an important factor in farm expenditures the stations should aid the farmer in the intelligent purchase and application of fertilizers. He believed this to be the attitude assumed by most of the experiment stations, and that the position needed no defense. W. H. Jordan stated that while he recognized that there are manufacturers and agents who stand on as sound and dignified a basis in what they say and do as any other class of men, he was personally cognizant of methods and arguments in vogue which made it incumbent upon the experiment stations of his State to secure better methods of trade than those now prevailing; and he believed the New York Station or any station in the Eastern States—he could not speak as to the West—could do for the farmers no better service than to point out to them more efficient and economic methods of purchasing plant food. The attitude of the stations had been not so much directly antagonistic to the purchase of commercial fertilizers, as an attempt to point out to the farmers of the Eastern States the value of their home resources. He wished to disclaim on the part of eastern experiment stations, as far as he had any authority to speak for them, any such position as antagonism to the judicious and economical use of commercial fertilizers.

¹ This paper has been published in a series of articles in the *Ohio Farmer*.

I. P. Roberts read a paper on Productivity as affected by tillage, in which he showed that by the employment of better methods of tillage the soil supplies of fertility may be more largely utilized, and thus the necessity for applications of fertilizers may be greatly reduced.

H. P. Armsby read a preliminary account of feeding experiments at the Pennsylvania Station which are reported in detail elsewhere.¹

The report of the committee on uniform fertilizer legislation was submitted by H. J. Wheeler, and adopted as submitted. The recommendations of the committee will be found elsewhere (E. S. R., 10, p. 506). The only portion of this report which called out any discussion was that relating to the form of guarantee of phosphoric acid, but the recommendation of the committee on this point was finally adopted.

H. J. Wheeler read a paper on The possibility of drawing erroneous conclusions from plant-soil tests. In this paper, which was based upon the results of experiments at the Rhode Island Station, attention was called to the unreliability of soil tests with fertilizers under certain conditions, e. g., with a deficiency of lime or of available phosphoric acid. Attention was called to the fact that the value of lime as a liberator of inert phosphoric acid may be, in certain soils, of more far-reaching importance than is generally supposed.

This paper gave rise to considerable discussion, in which the danger of drawing hasty conclusions from experiments with fertilizers was strongly emphasized.

A paper on The significance of stock-feeding experiments was read by C. F. Curtiss. This paper discusses the progress made in applying scientific principles to practical stock feeding in the United States, and points out the practical value of feeding experiments by the stations in showing the feeder how to raise a better product at a less cost and how to get the greatest return for the feed consumed under varying conditions. In many cases, however, work of this character has been superficial. It should be made more thorough and confined to a few definite lines.

The report on nomenclature was submitted by H. P. Armsby. Two questions are considered in this report: (1) The terms "concentrates" and "roughage" as applied to feeding stuffs by Henry, and (2) the nomenclature of nitrogenous compounds. As regards the first, the committee was of the opinion that action by the Association was unnecessary. As regards the second, the committee recommended "for present use certain collective terms," as follows:

- | | | | |
|---------------|---|----------------|--|
| PROTEIN . . . | { | Proteids . . . | 1. Albuminoids (albumins, globulins, coagulated and compound proteids, and other cleavage products down to and including peptones). |
| | | Nonproteids | 2. Collagens or gelatinoids (collagen, elastin, and related nitrogenous bodies specially characteristic of connective tissue). |
| | | | (a general term for noncoagulable nitrogenous matter, including nitrogenous extractives in the animal, and amids and similar bodies in the plant). |

¹ Pennsylvania Sta. Bul. 42.

A paper on The nomenclature of nitrogenous compounds of animal and vegetable substances was presented by W. O. Atwater.

The paper by M. A. Scovell, previously referred to (p. 708), was very fully discussed in a session of the section.

J. S. Newman read a paper on The relation of the land-grant colleges to the experiment stations viewed from the standpoint of the agriculturist.

SECTION ON HORTICULTURE AND BOTANY.

In this section B. D. Halsted discussed the relations of climate and rainfall to prevalence of fungus diseases, displaying a chart showing the monthly rainfall, April to September, for ten years (1889-1898), and pointing out the coincidence between seasons of heavy rainfall and severe outbreaks of fungus diseases.

L. C. Corbett read a paper on Laboratory methods in teaching horticulture, in which the advantages of such methods were pointed out.

The committee on cooperative tests of different races of peaches submitted a progress report, giving an account of the organization of cooperative work in this line with 24 experiment stations in 4 belts running north and south across the United States—2 east of the Mississippi River and 2 west of that river. Tests are to be made of 3 varieties of each of 5 races of peaches¹—Peen-to, South China, Spanish, North China, and Persian.

S. M. Emery discussed the subject of fruit testing by experiment stations.

J. Craig presented the rules for pomological nomenclature adopted by the Horticultural Lazy Club of Cornell University.² After a full discussion of the subject it was voted that a permanent committee of five, to be known as a committee on nomenclature, be appointed to have charge of matters pertaining to horticultural nomenclature. The committee appointed is F. A. Waugh, J. Craig, W. A. Taylor, L. R. Taft, and G. H. Powell.

A joint session of this section and of the section on entomology was held to consider the subject of inspection of nursery stock and trees. The discussion of this subject was opened by a paper by W. E. Britton on Nursery inspection in Connecticut. This paper reviewed the work accomplished under the peach yellows law enacted in 1893 and repealed in 1897. While the work of the peach yellows commission appointed under this law was very effective, there is little immediate prospect of securing the enactment of other laws of this character in Connecticut. The Connecticut State Experiment Station has, however, undertaken inspection work on its own responsibility, and in many cases at the request of the nurserymen themselves, who find it desirable to have certificates of inspection. A number of examples are cited to

¹ U. S. Dept. Agr., Office of Experiment Stations Bul. 49, p. 82.

² Amer. Gard., 19 (1898), p. 712.

show the difficulties encountered in such work. The San José scale has been found to be quite widely disseminated in the State. As a rule left-over stock is more likely to be infested than the newer stock. Uniform laws and systems of inspection are much to be desired.

In discussing this subject J. B. Smith said that he considered the inspection of nursery stock a most unsatisfactory duty. His experience had been that the certificates of inspection were worthless, and he would be glad to see the system done away with and written guaranties of nurserymen substituted. W. G. Johnson gave an account of the success attending the inspection work and hydrocyanic-acid gas treatment in Maryland. The discussion was participated in by a number of others, the general opinion apparently being that inspection certificates are not reliable.

SECTION ON ENTOMOLOGY.

In the section on entomology a paper was read by C. M. Weed on The relation of nature studies in the schools to the biology of the college curriculum. This paper discussed briefly the historical development of the study of the natural sciences in American schools and colleges, showing the advance in the last 50 years.

SECTION ON MECHANIC ARTS.

The first paper read in this section was by O. L. Waller, entitled What shall be the character of the preparatory work required to enter four-year engineering-degree courses? By a vote of the section this paper was selected to be read in the general session (see p. 708).

A paper on Engineering standards and land-grant colleges, by W. H. Williams, was read by the secretary.

F. P. Anderson gave a brief account of tests which are being made at the Kentucky College of the hauling power and fuel consumption of locomotives.

The preceding account shows very clearly that by far the larger portion of the time of the convention was devoted to the consideration of questions of college policy and methods of teaching. The number of technical papers dealing with experimental methods and the results of investigation was relatively small as compared with previous conventions. The fact, however, that the convention voted decisively, in its action on revision of the constitution, against making the Association purely administrative in function would indicate that there is no abatement of its interest in investigational methods and results and no purpose to neglect this feature of its work.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

The determination of citrate-soluble phosphoric acid in Thomas meal, J. FREUNDLICH (*Chem. Ztg.*, 22 (1898), No. 92, pp. 974, 975).—In a recent article P. Wagner proposed a new method for determining citrate-soluble phosphoric acid in Thomas slag, using citric acid instead of ammonium citrate. He pointed out that care should be taken to prevent the precipitation of silica along with the ammonium-magnesium phosphate, when the magnesia mixture is added.

This writer calls attention to another adulteration, which Wagner does not mention, viz, iron sulphid. By the action of the citric acid on the sulphids so often present in the slag, hydrogen sulphid is formed. When ammonia is added ammonium sulphid results, which, reacting with iron citrate, forms iron sulphid. To avoid weighing this with the ammonium magnesium phosphate, two precipitations are necessary, the iron sulphid in the first precipitate being oxidized by nitric acid or aqua regia.—J. T. ANDERSON.

Reynoso's method of analysis of phosphates, U. ANTONY and G. H. MONDOLFO (*Gaz. Chim. Ital.*, 28 (1898), pp. 142-147; *abs. in Jour. Soc. Chem. Ind.*, 17 (1898), No. 12, p. 1186).—In this method phosphoric acid combined with alkaline earths is removed by treating the ammonia precipitate with tin and nitric acid. The precipitate is heated with 77 per cent nitric acid and tin foil, cooled, filtered, and excess of ammonia added. The precipitate contains all the aluminum present and the filtrate the alkaline earths.

“From the precipitate which, in presence of phosphoric acid, is formed by tin and nitric acid, concentrated hydrochloric acid dissolves a compound which contains the phosphoric acid in the ratio $\text{PO}_3:7\text{Sn}$, is soluble in alkalis, precipitated from alkaline solution by carbon dioxide, and is called by the authors phosphostannic acid. Tin and nitric acid react in presence of iron to form a compound slightly soluble in hydrochloric acid and soluble in cold alkalis, but precipitated as ferric hydrate, on boiling the alkaline solution. If the reaction takes place in presence of phosphoric acid, ferric phosphostannic appears to be formed.”

A study upon the phosphoric acid dissolved in the soil solutions, T. SCHLÖESING, JR. (*Compt. Rend. Acad. Sci. Paris*, 127 (1898), No. 4, pp. 236-239; 6, pp. 327-329).—From a study of various methods of extracting soluble phosphoric acid from soils, the author concludes that shaking a given amount of soil with a fixed amount of water is a more reliable means than leaching with successive portions of water. The

method proposed is as follows: Shake 300 gm. of the soil for 6 hours with 1,300 cm. of water in a 1½ liter flask, placed horizontally in a rotary machine making 2 revolutions per minute. Filter off 1 liter of the solution for the determination of phosphoric acid. The nature of the water used (even the presence of considerable amounts of carbon dioxide or bicarbonates) apparently has no great effect upon the result.

The amount of soluble phosphoric acid found by this method in different soils was very small, rarely exceeding 0.001 gm. per liter of extract, or 0.45 kg. per hectare. It appears that the amount of soluble phosphoric acid which water will remove from soil is the result of an equilibrium of two opposing classes of chemical action; one class tending to render the phosphoric acid insoluble, the other to make it soluble. This tendency toward equilibrium is believed to cause a constant renewal of soluble phosphoric acid in the soil as fast as it is used by the plants. Thus while the amount of phosphoric acid in this form in the soil at any given time is found to be exceedingly small, it is by no means unimportant as a factor of plant food supply.

Determining the density of sugar cane, A. A. RAMSAY (*Queensland Agr. Jour.*, 3 (1898), No. 5, pp. 359-361).—The author recommends that a few canes, from 3 to 8, which apparently represent the average crop be selected and split into quarters longitudinally, one quarter being used for the extraction of the juice. The density of the thoroughly mixed juice from the different canes is determined by means of a saccharimeter or Brix spindle, the temperature of the juice being kept at about 20° C. In estimating the total soluble solids in the cane from the density thus determined it is assumed that the cane contains 10 per cent of fiber saturated with 90 per cent of juice. The equation thus becomes

$$\text{Soluble solids in cane} = \text{Density of juice} \times \frac{90}{100}$$

The proteids of cream, E. F. LADD (*Jour. Amer. Chem. Soc.*, 20 (1898), No. 11, 858-860).—In determining the casein, albumen, albumoses, and peptones in cream, the author dilutes 10 gm. of cream with 80 cc. of water and precipitates the casein with 3 cc. of saturated alum solution, the albumen in the filtrate by heating, the albumoses by saturating the filtrate with zinc sulphate, and the peptones by partially evaporating the filtrate and adding 80 per cent of the volume of absolute alcohol. Analyses are given of 1 sample each of fresh and ripened cream, the latter quite sour and ready for churning. These indicate that "the loss in working by these methods was not great, and further that there is not a very marked change in the proteids of cream during the process of ripening."

The fundamental principles of agricultural chemistry, R. OTTO (*Grundzüge der Agrikulturchemie. Berlin: Paul Parey, 1898, pt. 1, pp. 160, figs. 14*).—The work is intended for agricultural, forestry, and horticultural schools, as well as for self-instruction. This part is devoted to a discussion of the subjects of air and soil.

Some records of the year's progress in applied chemistry, W. McMURTRIE (*Jour. Amer. Chem. Soc.*, 20 (1898), No. 12, pp. 967-987).

Report of the chemist, E. FULMER (*Washington Sta. Rpt. 1896*, pp. 45-56).—This is a brief summary of the work of the year ending June 30, 1896, and includes analyses of clays, chloropal, flaxseed, alum, limestone, hematite, cottonwood ashes, mineral water, coal, peat, fir ashes, water from city supply of Ballard, Washington, potatoes, Paris green, starfish ashes, corn juice, dried blood, bone, 7 samples of mixed fertilizers, muriate of potash, sulphate of potash, double manure salt, kainit, and conglomerates. Brief summaries are also given of results of investigations on the nitrogen content and humus of Washington soils (E. S. R., 9, p. 33).

Laboratory notes, F. H. STORER (*Bul. Bussey Inst.*, 2 (1898), VII, pp. 409-421).—These include the determination of wood gum in the "doty" wood of the birch; the estimation of cellulose, lignic acids, xylan, and wood gum in peach stones; extraction of wood gum from the trunks of coniferous trees by cold dilute alkaline solutions; wood gum in the strawberry; the question of the presence of xylan in the membranous covering of the starch grain; and an analysis of a sample of ashes left on burning the bamboo baskets in which sugar is exported from Java.

Micro-chemical detection of perchlorates in nitrate of soda, M. VAN BRUKELEVEEN (*Rec. Trav. Chim., Pays-Bas*, 17 (1898), pp. 94, 95; *Bul. Soc. Chim. Paris*, 19 (1898), No. 20-21, p. 863; *abs. in Jour. Chem. Soc. [London]*, 74 (1898), No. 431, II, p. 482).—The method proposed is as follows: Distil 10 gm. of nitrate in 100 cc. of water, add 50 cc. of 95 per cent alcohol, boil, and let stand for 2 hours to crystallize. Filter, evaporate to dryness, distil the residue in the least possible quantity of water, and test by Behren's method (mixing the solution with rubidium chlorid on a microscope slide and coloring (red) the rhombic crystals formed with potassium permanganate).

On the ignition of ammonium-magnesium phosphate with the filter paper, H. MASTBAUM (*Ztschr. Analyt. Chem.*, 73 (1898), pp. 581, 582).—The author places the filter while still wet in a crucible and heats at once in the full flame of a Bunsen burner, usually for 15 to 20 minutes, adds 2 or 3 drops of nitric acid, heats gently until the acid is expelled and then for a half a minute in the full flame. This method is considered rapid and convenient and fully as accurate as that proposed by Schmoeger,¹ in which the filter with the precipitate is dried in an oven before ignition.

The use of formaldehyde for the determination of noncoagulable albuminoids, especially as applied to the analysis of gelatin, A. TRILLAT (*Bul. Assoc. Chim. Suer. et Distill.*, 16 (1898), No. 6, pp. 544-546).

Purification and decolorizing of sugar solutions by ozone, by electrolysis, and by both simultaneously, F. PETERS (*Ztschr. Elektrochemie*, 5 (1898), p. 265; *abs. in Jour. Phys. Chem.*, 3 (1899), No. 1, p. 65).—It was found that sirups were purified very much more effectively by the simultaneous action of ozone and of electrolysis than by either method taken singly.

Method of preparing protein from solutions, especially those from spirits, yeast, sugar, and starch manufactories, A. GLASER (*Neue Ztschr. Rübenz. Ind.*, 41 (1898), No. 15, pp. 160, 161).—The process has been patented in Germany.

A chemico-physiological study of certain derivatives of the proteids, R. H. CHITTENDEN, L. B. MENDEL, and Y. HENDERSON (*Amer. Jour. Physiol.*, 2 (1899), No. 2, pp. 142-181, *figs.* 9).—The physiological effect of the cleavage products of antialbumids, antialbumoses, antipeptones, and other similar products derived from egg albumin and gelatin are reported, as well as studies of the chemical nature and general properties of these proteids.

The most important vegetable foods and condiments, A. E. VOGL (*Die Wichtigsten Vegetabilischen Nahrungs- und Genussmittel. Vienna: Urban & Schwarzenberg, 1899*, pp. XV + 575, *figs.* 271).—This volume, which is the outcome of the author's connection with the *Entwürfe für einen Codex alimentarius Austriacus*, is a manual

¹Ztschr. Analyt. Chem., 73 (1898), pp. 308-310.

of the microscopical analysis of foods and condiments. Special attention is given to determining the purity of such materials and the detection and identification of the principal impurities and adulterants. Chapters are devoted to the analysis of flours and other milling products of cereals and leguminous seeds, and starches and sago, vegetables, fruits, tea, coffee, cocoa and similar products and spices. A chapter is also devoted to directions for recognizing with the microscope the more common adulterants of powdered spices.

Practical guide to the analysis of water, W. OEHLMÜLLER (*Guide pratique pour l'analyse de l'eau*. Paris: Librairie Polytechnique Baudry et Cie, 1898, pp. 289, pl. 1, figs. 77).—Translated by L. Gautier from the second German edition of *Die Untersuchung des Wassers*.

Determination of organic substances in water, A. PAGNOUL (*Ann. Sci. Agron.*, 1898, II, No. 1, pp. 95, 96).—Water containing, as a rule, 20 mg. of organic matter in various forms was tested with permanganate of potash immediately after preparation, and after standing 40 days in an open flask exposed to sunlight and in a closed flask in darkness. The results were very discordant and indicate that there is no reliable factor for calculating organic matter from oxygen absorbed.

On the facilities for standardizing chemical apparatus afforded by foreign governments and our own, L. A. FISCHER (*Jour. Amer. Chem. Soc.*, 20 (1898), No. 12, pp. 912-927, pls. 2).—In addition to describing these facilities and discussing the standardizing of chemical apparatus, the author describes a device used by the Office of Standard Weights and Measures for making flasks, and recommends the adoption of the following units of measurement:

"(1) The liter, as defined by the International Committee of Weights and Measures, viz, the volume of the mass of a kilogram of pure water at the temperature of maximum density, and under a pressure of 760 mm. of mercury.

"(2) Density, defined as the ratio of the mass of a substance to that of an equal volume of pure water at its maximum density (4° C.).

"(3) The centigrade degree of the hydrogen thermometer of the International Bureau of Weights and Measures.

"I also recommend that some convenient temperature be adopted, at which all volumetric apparatus shall contain their stated capacities."

Extraction apparatus for laboratories, B. DONNER (*Chem. Ztg.*, ?? (1898), No. 94, p. 996, figs. 2).—A convenient arrangement by which any number of extraction liquids may be used in succession on a given substance, without transferring it from one containing vessel to another. With one adjustment of the parts the apparatus acts as an ordinary continuous extraction apparatus. By substituting for the distillation flask with the extraction liquid another containing water and making a slight readjustment of the condenser, we have a steam drier so arranged that the liquid left in the substance is vaporized and is then recondensed and collected.—J. T. ANDERSON.

A new electric agitator, E. VAN MELCKEBEKE (*Bul. Assoc. Belge Chim.*, 12 (1898), No. 9, pp. 331-334, fig. 1).—The stirring rods are attached to a metal rod carried by an armature oscillating between 2 electro-magnets, so arranged that the stirring rods may be given either a backward and forward or a rotary motion.

An improved apparatus for the estimation of carbonic acid in minerals, etc., A. MARSHALL (*Jour. Soc. Chim. Ind.*, 17 (1898), No. 12, pp. 1106, 1107, fig. 1).—A method depending upon the measurement of the volume of gas evolved is described.

A new crucible—the tube crucible, E. MURMANN (*Monatsh. Chem.*, 19 (1898), p. 403, fig. 1; *abs. in Jour. Soc. Chem. Ind.*, 17 (1898), No. 12, p. 1181).—The crucible has a perforated bottom, ending in a straight or bent tube.

Collen's device for recovering the ammonium sulphate from coke ovens (*L'Engrais*, 13 (1898), No. 44, p. 1046).

BOTANY.

Economic grasses, F. LAMSON-SCRIBNER (*U. S. Dept. Agr., Division of Agrostology Bul. 11, pp. 85, figs. 91, pls. 3*).—This bulletin contains brief descriptions of 252 of the more important species of native and introduced grasses. Much of the matter presented has been published in a former bulletin (*E. S. R.*, 8, p. 687). In the list of grasses for special soils or uses 38 species are given as hay grasses, 36 as pasture grasses, and 15 as lawn grasses; 25 as suitable for wet lands, 20 for embankments, and 20 for holding shifting sands. The descriptions of the species are arranged alphabetically according to scientific names, and a list of the common English or local names of the species also arranged alphabetically serves as an index. Some of the species suitable for lawns and shifting sands are discussed in other publications (*E. S. R.*, 7, p. 492; 10, p. 551).

A report upon the forage plants and forage resources of the Gulf States, S. M. TRACY (*U. S. Dept. Agr., Division of Agrostology Bul. 15, pp. 55, figs. 20*).—The author briefly discusses and classifies the soils of the region and also its natural pastures. In the formation of pastures the essentials of a good pasture, selection of varieties, care of pasture lands, temporary pastures, and winter pastures are described. The value of alfalfa, Bermuda grass, cowpeas, crab grass, German millet, Johnson grass, and red clover for meadows is stated and various crops for soiling and fodder are mentioned. Some 60 grasses and 40 miscellaneous forage plants are described in greater or less detail as the more important hay and pasture plants of the region.

The Red Desert of Wyoming and its forage resources, A. NELSON (*U. S. Dept. Agr., Division of Agrostology Bul. 13, pp. 72, pl. 5, figs. 24*).—The author describes the location, extent, topography, geology, soils, climate, water supply, extent of settlement of the Red Desert, and indicates the different plant formations existing in that region. The amount and quality of forage is commented upon and suggested means for its improvement are given. The characteristic plants of the region are enumerated, and the winter range is said to consist largely of salt sages, sagebrushes, wheat grasses, Indian millet, giant rye grass, and the desert juniper. The vegetation of the hill country or summer range consists largely of species of *Poa*, brome grasses, drop seed, reed meadow grass, redtop, and sedges. Descriptive lists are given of the various forage plants of the summer range, and a general flora of the Red Desert completes the publication.

On the rôle of the awns of Gramineæ, N. I. VASILYEV (*Zap. Novo-Alexandri Inst. Selsk. Khoz. i Lyesor.*, 10 (1897), No. 2, pp. 119-168).—The author undertook to verify the conclusions of Zoebel and Mikosch relative to the rôle of the beards as evaporating organs, also to ascertain whether this property is peculiar to the beards during certain periods of their development, and whether this peculiarity, which is so characteristic of the beards of barley, is possessed by other cereals. His

experiments were conducted upon varieties of the following plants: *Triticum durum*, *T. vulgare*, *T. amyleum dicoccum*; rye, barley (*Hordeum vulgare*, *H. distichum*, *H. tetrastichum*), and *Stipa capillata*. The experiments were conducted by cutting under water the heads from the stalk and placing them in test tubes of distilled water, the heads being supported by a wire so that the stalks did not reach the bottom of the test tube. Vegetable oil was poured over the water to prevent its evaporation. From some of the heads the beards were removed; others remained intact. The experiments were continued 2 to 3 hours and frequent weighings were made. The amount of evaporation was calculated to the unit of weight of the head.

Summing up his investigation, the author concludes that when the beards are large at certain stages of development they evaporate the greater amount of water given off by the head, and cutting off the beard strikingly diminishes the transpiration. In experiments with Byeloturka wheat it was found that 63.3 per cent of the water transpired by the head was from the beards, and in another variety 60.3 per cent of the total water evaporated was transpired through the beards. In his experiments with *Stipa capillata* 67 per cent of the total was given off through the awns.

The intensity of evaporation is a temporary phenomenon possessed by Byeloturka and black bearded wheat at the period of flowering, while in the case of *Stipa* it was most abundant at the time when the seed was in the milk stage. The percentage of transpiration by the beards of Byeloturka varies from 22 per cent during early stages to a maximum of 63.3 per cent and falls to 16.6 per cent during the period of ripening.

In relation to light, humidity, and the other factors which influence evaporation, the author finds that the beards are not particularly sensitive compared with other parts of the ear. The variation in the amount of evaporation the author thinks is probably due to changes in the anatomical structure of the beards, and suggests this can only be determined by a thorough study of their anatomy.

The removal of the beards from a part of the spikelets lowered the weight of grain as much as 9 per cent in one experiment, seeming to indicate that the presence of the beards is favorable to the proper filling of the grain.—P. FIREMAN.

On the vegetative period of plants, L. P. NILSSEN (*Tidsskr. Norske Landbr.*, 5 (1898), No. 5, pp. 283-286).—The writer discusses the question of the length of the vegetative period of cultivated plants in the far north, as compared with that in more southern regions. Without giving much direct evidence or results of prolonged observations, he maintains that the popular idea is erroneous that owing to the prolonged light during the summer months at the arctic circle plants mature more rapidly there than farther south. While the average growing period for six-rowed barley is placed at about 95 days for southern Norway, and for oats about 112 days, he finds that the period

is, on the average, for Nordland's *amt* (Norway, 65 to 69° latitude), for barley 103½ days, oats 113¼ days, spring rye 111 days. While light is a potent factor in plant growth, it is only one of the important factors; a sufficient supply of heat and moisture are as essential, and northern regions are especially at a disadvantage as regards the former.—F. W. WOLL.

A study of the roots of perennial plants, E. S. GOFF (*Wisconsin Sta. Rpt. 1897, pp. 286-298, figs. 6*).—The author states that while the root growth of many annual crops has been more or less thoroughly investigated, the study of roots of perennial plants seems to have been to a large extent neglected. A modification of the root cage previously described (E. S. R., 5, p. 480) was made. In order to expose the roots more fully to view, instead of the iron cage there described, a wide board was used and wires thrust through holes bored through it. This apparatus was soon found to be unsuitable, and a slatted frame was substituted for the boards with perfect success. Studies were made of the roots of strawberry, raspberry, grape, and apple trees.

The roots of the strawberry were contained within a very small compass, the deepest extending a little less than 2 ft., while the horizontal roots reached scarcely beyond the area covered by the leaves. This limited root range of the strawberry plant readily explains its well-known susceptibility to drought, as well as its ready response to fertilizers. These studies emphasize the importance of providing for irrigation wherever large and regular crops are to be depended upon and also suggest the importance of a method of culture whereby the rows of plants should be slightly lower than the spaces between the rows.

The roots of the raspberry were found to extend horizontally a distance of 4 ft., and vertically something more than 5 ft. The shallowness of the main root is noticeable, as well as the large number of vertical roots. The shallow depth traversed by the main root would suggest the inadvisability of too deep plowing between the rows.

The author states that as the grapevine is not required to support its own trunk and in culture is heavily pruned each year, he had anticipated rather shallow and scanty root development. It appears, however, that almost no roots were found at a depth less than 18 in. The main root continued something more than 13 ft. Dead roots in the upper layers of soil were frequently observed. Whether these shallow roots had been destroyed by severe freezing or whether they had perished on account of the severe drought of 1894 and 1895 is unknown. Below the main root the whole system seemed to be alive and for the most part in excellent condition. The soil was rather light clay loam to a depth of about 2 ft.; below this was a layer of sandy clay, 2½ ft. thick, resting on a stratum of heterogeneous drift gravel consisting of loose sand mingled with pebbles mostly of small size, but a few larger than a man's fist. The longer vertical roots extended with comparatively few branches into this gravel stratum. The numerous white root tips indicated that the roots were active at a depth of 6 or 8 ft.

The roots of several apple trees were examined, one of which had been planted 7 years on a rather poor soil. The larger roots varied from $1\frac{1}{4}$ to 2 in. in diameter, and the root system extended horizontally on one side a little more than 12 ft. and vertically about 9 ft., from which it appears that the tree drew its sustenance from a cylinder of soil something more than 24 ft. in diameter and 9 ft. in depth, representing a total volume of about 150 cubic yards. Comparisons were made between a seedling tree 4 years old and 2 root-grafted trees 3 years from the graft. The difference in the forms of the crown of the root was found to be quite marked in the 2 methods of growth. In the seedling no abnormal growth was perceptible, while in the part of the trees grown from root grafts the growth of the crown was abnormal. In the seedling a strong tap root was developed, while in the root grafts there was no semblance to a tap root. If these abnormal growths generally follow root grafting, the author suggests that some substitute for this system might prove acceptable in the northwestern States.

Evaporation and plant transpiration, W. MAXWELL (*Jour. Amer. Chem. Soc.*, 20 (1898), No. 7, pp. 469-483).—The author reports experiments on the amount of moisture directly evaporated from the soil, and the relative proportion that escapes by transpiration from sugar cane during the different periods of growth. The methods followed in the experiments were briefly as follows: One hundred and twenty-five pounds of a particular soil was placed in each of 2 tubs with perforated bottoms, over which a piece of linen cloth was laid before putting in the soil to prevent the earth falling through or blocking up the holes. When filled with soil the tubs were set into galvanized iron pans containing water which was kept at a constant level. The pans were covered with moisture-proof glazed cloth to prevent any evaporation from the water surface. All evaporation of water would necessarily have to take place through the surface of the soil and the transpiration of the plant. In one tub 3 pieces of seed cane were planted, while the other was kept as a check. The tubs were placed upon a veranda having a southern exposure with a strong light, but protected against rainfall. The mean outdoor and indoor evaporation, humidity, direction of the wind, and other meteorological data were secured, which, together with the amount of evaporation from the 2 tubs, is tabulated.

The experiment was continued for $7\frac{1}{4}$ months. The water evaporated from the soil in tub No. 1 was 83,140 gm., and the water evaporated from the soil and transpired by the cane in tub No. 2 was 167,250 gm., thus showing that the cane transpired during the period indicated 84,110 gm. As the total amount of dry matter produced during the period of growth was 568.9 gm., for each gram of water-free sugar cane material produced 147.8 gm. of water was transpired. The amount of water transpired by the plant is given by monthly periods, and from the data collected the author thinks some important conclusions relative to practical irrigation could be drawn. "To apply the

same volume of water at the time of planting and during the early period of growth, when transpiration is very low, that is required by the cane later in development, incurs a great loss of water and of soil constituents that the water removes."

The fertilization of cultivated legumes, C. FRUWIRTH (*Ueber Befruchtungsverhältnisse bei Hülsenfrüchten. Pflanzungen: Friedrich Find, 1898, pp. 50*).—The floral biology of the cultivated legumes in general is discussed and a detailed study according to the methods of Darwin, Herman Müller, and Delpino is made of about 30 species of economic importance, and notes given on adaptation to cross fertilization and on insect visitors. Three brief series of experiments were performed to determine to what extent cross fertilization is necessary for each species, (1) legumes grown in the field being covered with netting, (2) single plants grown in an inclosed space, and (3) single flowers in the field covered. The results of these experiments are given in the individual discussion of each species. Various notes on order of opening of the inflorescence, crossing, and setting of fruit are interspersed. These investigations developed the fact that in most species of legumes self-fertilization takes place quite readily. It was found that a relatively small setting of fruit in many species is not due so much to lack of insect visitors as to exceptional causes. Covering the plants does not exclude small creeping insects, and probably these are important agents in cross fertilization. Of those species in which self fertilization could not be demonstrated much less fruit set on covered plants than on others.

Alinit, GERLACH (*Chem. Ztg., 22 (1898), No. 77, p. 789*).—A brief abstract of a paper read before the German Association of Naturalists and Physicians. An examination of samples of this material showed that instead of being a pure culture, as is claimed, various organisms were present, among which are mentioned a bacillus similar to the hay bacillus, a sarcina, a species of red yeast, and an organism similar to the potato bacillus.

Culture experiments were undertaken to test the effect of this substance in growing barley, rye, wheat, and white mustard, but no improvement due to the inoculating substance was found. In the discussion following the reading of the paper, Tacke, Wilfarth, and Nobbe, agreed with the author that Alinit was without beneficial effect in aiding in the nitrogen assimilation of cereals, etc.

Experiments with Nitragin, E. WOLLNY (*Vrtljschr. Bayer. Landw. Rath., 3 (1898), No. 2, pp. 171-184*).—The author concludes from his investigations that soil inoculation with Nitragin or material from fields where leguminous crops have been successfully grown gives little or no increased yield in humus soils. Upon poor soils and especially upon sandy soils inoculation may prove successful, but similar or even more striking results might have been obtained with fertilizers. Inoculation where yellow lupines, serradella, or other calcifugous Leguminosæ are

grown on lime soils, is without effect, while the proper application of combined nitrogen in suitable fertilizers will prove advantageous in increasing plant growth. In general a small quantity of nitrogenous fertilizer may be profitably added to soils where root tubercle bacteria are present in considerable quantity.

On the assimilability of organic nitrogen in sterilized media, A. LYEBYEDYEV (*Selsk. Khoz. i Lyesor.*, 186 (1897), No. 7, pp. 159-169).—Sand cultures were conducted with barley in which 2 seeds were planted in each of 11 vessels, the sand having been previously sterilized by ignition and washed with hydrochloric acid. The sources of nitrogen supplied were urea, hippuric acid, leucin, aspartic acid, and asparagin. Carbonate of lime was added so as to render the different cultures as nearly neutral as possible. Part of the vessels were sterilized; the others not. To the lots which were not sterilized a few drops of aqueous soil extract were added. All the seeds, whether in sterilized or nonsterilized vessels, were placed for one minute in a 5 per cent solution of corrosive sublimate before planting. During the experiment, which lasted from July to September, particular pains were taken that the water which was given the plants should in no way convey bacteria to the cultures. The results obtained are shown in the following table:

Assimilation of organic nitrogen by barley.

Source of nitrogen.	Not sterilized.					Sterilized.				
	Weight of water-free substance.			Number of grains.	Average weight per grain.	Weight of water-free substance.			Number of grains.	Average weight per grain.
	Roots.	Straw.	Grain.			Roots.	Straw.	Grain.		
	<i>Grams.</i>	<i>Grams.</i>	<i>Grams.</i>		<i>Gram.</i>	<i>Gram.</i>	<i>Gram.</i>		<i>Gram.</i>	
Hippuric acid ...	0.273	0.819	0.018	5	0.0036	0.006	0.017	
Urea.....	.112	.666013	.032	
Leucin.....	1.101	2.028	1.117	43	.024	.071	.223	
Asparagin.....	.528	1.688	.726	42	.017	.211	.346	0.153	5	
Aspartic acid.....	.257	1.327	.366	29	.013	(a)	
Calcium nitrate...	1.512	4.630	3.945	79	.05	(b)	

a Vessel holding culture broken.

b No duplicate of this lot in sterilized sand.

From the above table it is shown that under the conditions of this experiment the seeds germinated in sterilized media, but with the exception of those which had received asparagin were unable to develop their plants to any considerable extent. The experiment, however, corroborates the claim that in sterilized media plants can obtain some nutrition from organic compounds containing nitrogen.—P. FIREMAN.

The geographical distribution of cereals in North America, C. S. PLUMB (*U. S. Dept. Agr., Division of Biological Survey Bul. 11, pp. 24, map 1, figs. 3*).—The author has sought to give the distribution of varieties of corn, wheat, and oats adapted to the different life zones as elaborated by Dr. Merriam of this Department. The information upon which this work is based was secured by sending blanks to about 2,500 grain growers throughout the United States and Canada. From the

replies received, which numbered 1,033, it appears that in many localities but little attention is paid to keeping varieties pure, and many farmers use mixed, unknown, or local varieties of ordinary merit for seed. The gradual acclimation of cereals through years of selection and cultivation is claimed to have produced varieties much better adapted to one zone than another, and upon this theory the author has mapped the distribution of 15 varieties of corn, 13 of wheat, and 7 of oats.

Life zones and crop zones of the United States, C. H. MERRIAM (*U. S. Dept. Agr., Division of Biological Survey Bul. 10, pp. 79, map 1*).—The present report is designed to explain the relations of the study of the geographical distribution of the native animals and plants to practical agriculture. The bulletin is divided into four parts as follows: (1) Relations of the Biological Survey to practical agriculture, (2) life zones of the United States—boundaries, native species, and important crops, (3) laws of temperature control of the geographic distribution of animals and plants, and (4) crop tables.

The first part is a reprint from the Yearbook of this Department for 1897; part 2 discusses the life zones of the United States, their boundaries, native species, and important crops. As recognized by the author, the life zones of the United States are 6 in number, with several minor subdivisions. In the third part the author states his views relative to the effect of temperature in controlling geographical distribution of animals and plants, and gives the following law based upon his investigations: "The northward distribution of terrestrial animals and plants is governed by the sum of the positive temperatures for the entire season of growth and reproduction, and the southern distribution is governed by the mean temperature of a brief period during the hottest part of the year." The sum of the positive temperatures is secured by adding together for the entire growing period the average daily temperature in excess of 6° C. (43° F.). The length of period which controls the southern distribution has not been definitely determined, but it is thought to be approximately the 6 hottest consecutive weeks. In the table showing the governing temperatures of zones, instead of the sum of the normal mean daily temperatures above 6° C., as stated, the figures given are those of the total temperatures for the entire growing period. Attention has been called to this.¹

In the fourth part of the bulletin the zone ranges are given for the more important varieties of cereals, and for apples, apricots, cherries, grapes, peaches, pears, plums, strawberries, nuts, etc. In compiling these ranges it became apparent that some varieties extend over wide areas, thriving in many zones, while a few are confined to a single zone.

On plant culture and plant diseases, M. F. NILSSEN (*Tidsskr. Norske Landbr., 5 (1898), No. 5, pp. 241-282*).—Report of work done by Swedish and Danish experiment stations in plant culture and plant diseases.

¹Science, n. s., 9 (1899), No. 212, p. 116.

Meadow plants of Central Franconia, R. BRAUNGART (*Vrtljschr. Bayer. Landw. Rath.*, 3 (1898), No. 1, p. 52).—Gives notes on the occurrence and relative value of the grasses, leguminous plants, and weeds growing in meadows.

Eragrostis brownii as a forage plant, J. H. MAIDEN (*Agr. Gaz. New South Wales*, 9 (1898), No. 10, pp. 1131, 1132).—The value of this grass as a forage plant is questioned. Although growing well and withstanding heat it is said to be harsh and not readily eaten by stock.

Rhea, or China, grass, G. WATTS (*Agr. Ledger*, 1898, No. 15, pp. 129, pls. 4).—A review of the existing information relative to this plant, *Bahmeria nireca*.

A sand binding plant dangerous to horses, J. H. MAIDEN (*Agr. Gaz. New South Wales*, 9 (1898), No. 10, p. 1131).—Notes are given of *Gnephopsis eriocarpa*, which from its habit of growth is dangerous to horses, since in eating it they are liable to get large amounts of sand in their stomachs.

Trifolium pratense perenne and T. medium, F. NOBBE (*Mitt. Deut. Landw. Gesell.*, 13 (1898), No. 22, pp. 345, 346, figs. 2).—A note describing the difference between these clovers.

Notes on poisoning and poisonous plants (*Deut. Landw. Presse*, 25 (1898), No. 58, p. 645; 61, p. 673).

New or noteworthy Alabama fungi, F. S. EARLE (*Bul. Torrey Bot. Club*, 25 (1898), No. 7, pp. 359-368).—As a contribution from the Alabama Biological Survey the author has given important notes and descriptions of a number of species of fungi. Among those described as new are *Micropeltis alabamensis* on living leaves of *Magnolia virginiana*; *Anthostomella spherotheca* and *Gnomia sabalicola* on dead petioles of *Sabal adansoni*; *Botryosphaeria arundinaria* and *Trichosphaeria underwoodii* on dead stems of *Arundinaria*; *Metasphaeria nigromaculans* on dead stems of *Agave virginica*; *Nectria (Eunectria) melii* on dead twigs of *Melia azedarach*; *Aulographum confuens* and *Lophodermium rubicolum* on dead stems of blackberry; *Phyllosticta arida* on *Acer negundo*; *P. macroguttata* on *Meibomia* sp.; and *Cercospora ribis* on leaves of cultivated gooseberry. In regard to the last-named fungus the author says: "This conspicuous and well-marked species attacks the gooseberry foliage abundantly, causing it to fall prematurely. It is probably one of the causes of the failure of the fruit in this region."

Biological studies of Penicillium glaucum, F. GUÉGUEN (*Bul. Soc. Mycol. France*, 14 (1898), No. 4, pp. 201-255, pls. 4).

On the saprophytic development and cytological structure of the yeast-like sporidia of Ustilago maydis, R. MARIE (*Bul. Soc. Mycol. France*, 14 (1898), No. 4, pp. 161-173, pl. 1).

Structure of the fruit of some Gramineæ, P. GUERIN (*Jour. Bot. France*, 12 (1898), No. 23-24, pp. 365-374, figs. 12).—Studies are reported upon Eleusine, Dactyloctenium, Crypsis, Sporobolus, and Zizaniopsis, the fruit of each of which is said not to be a true caryopsis.

Studies of the flax fiber, A. HERZOG (*Oesterr. Chem. Ztg.*, 1 (1898), No. 1, pp. 310-312; 2, pp. 335, 336, figs. 7).—Microscopical and chemical studies are given of the flax fiber.

On the elongation of nodes, P. VAN TIEGHEM (*Ann. Scottish Nat. Hist. Soc.*, 8. ser., 5 (1898), No. 1-2, pp. 155-160).

Memoirs of the Institute of Forestry at St. Petersburg (*Izvyestia S. Peterburgskavo lyesnovo Instituta. St. Petersburg, 1898, pt. 1; rev. in Selsk. Khoz. i Lyesor.*, 190 (1898), No. 7, pp. 458, 459).—Of various articles in the publication, that on the liberation of heat by germinating seeds by A. Tolski may be mentioned.

On the growth of Nostoc punctiforme in absolute darkness, R. BOUILLIAC (*Compt. Rend. Acad. Sci. Paris*, 126 (1898), No. 22, pp. 1583-1586).—It is stated that this plant is able to grow in absolute darkness if provided with suitable organic material, such as glucose. Under these conditions it will produce green plants. The color, it is said, is due to chlorophyll, since the alga was able to decompose carbon dioxide and also as shown by spectrum analysis of the plants themselves.

The rôle of chlorophyll in sugar production (*Rev. Agr. Reunion*, 2 (1898), No. 9, pp. 437-439).—An important rôle in sugar production is shown for chlorophyll, and it is stated that the sugar content is lowered whenever the leaves are attacked by fungi or insects which cause a loss of chlorophyll.

So-called assimilation, C. R. BARNES (*Bot. Centbl.*, 76 (1898), No. 8, pp. 257-259).—Attention is called to the necessity of some specific word for the process of the manufacture of carbohydrates by plants. The author states that in 1893 he suggested photosyntax as such word. Photosynthesis has since been used by a number of writers, but the author objects to this word as etymologically less accurate than the term proposed by himself.

Concerning the assimilation of nitrates by phanerogams in the dark, U. SUSUKI (*Bot. Centbl.*, 75 (1898), No. 10, pp. 289-292).

On the synthesis of proteid materials by plants, W. PALLADIN (*Sep. Adbr. Arb. Naturf. Gesell. Univ. Charkov*, 33 (1898), pp. 8).

The formation of asparagin in the plant, E. SCHULZE (*Landw. Jahrb.*, 27 (1898), No. 3-4, pp. 503-520).

Root tubercles of leguminous plants, A. V. BERTHOUMIEU (*Rev. Sci. Bourbonnais*, 11 (1898), No. 129-130, pp. 166-175, pl. 1).

ZOOLOGY.

Cuckoos and shrikes in their relation to agriculture (*U. S. Dept. Agr., Division of Biological Survey Bul.* 9, pp. 26, pl. 1, fig. 1).—*The food of cuckoos*, F. E. L. Beal (pp. 1-14).—On the basis of an examination of a large number of stomachs, the food of cuckoos is described and a list is given of the insects identified. It is stated that from an economic standpoint cuckoos rank among the useful birds, since their diet consists very largely of insects and caterpillars found on trees and shrubs.

The food of shrikes, S. D. Judd (pp. 15-26).—The contents of the stomachs of a number of shrikes was examined and a list is given of the birds, mammals, and insects consumed. The author notes that although shrikes destroy birds, they destroy many mice and insects also. Their beneficial qualities are thought to outweigh their injurious qualities 4 to 1.

The winter food of the chickadee, C. M. WEED (*New Hampshire Sta. Bul.* 54, pp. 85-98, figs. 11).—The different insect eggs which chickadees eat are described, and observations on the abundance and food habits of chickadees in New Hampshire are reported. The investigations indicate that the chickadee should be encouraged, since throughout the winter it destroys large numbers of insect enemies of the farm, orchard, and garden.

The fact is pointed out that the presence of chickadees may be encouraged by suitable trees for shelter, and by placing suet or bones in trees where the birds may obtain them during the winter.

Feeding habits of the chipping sparrow, C. M. WEED (*New Hampshire Sta. Bul.* 55, pp. 101-110, fig. 1).—A careful record, covering one day, was made of the number of times a pair of chipping sparrows (*Spizella socialis*) left their nest, and the food which they brought to their young when they returned. The fact is noted that they frequently removed excrement from the nest.

"During this busy day the parent birds had made almost 200 visits to the nest, bringing food nearly every time, though some of the trips seemed to be made to furnish grit for the grinding of the food. There was no long interval when they were not at work, the longest period between visits having been 27 minutes. Soft-bodied caterpillars were the most abundant elements of the food, but crickets and crane flies were also seen, and doubtless a great variety of insects was taken. The precise determination of the most of the food brought was of course impossible, the observations having been undertaken especially to learn the regularity of the feeding habits of the adult birds. That they were busy from daylight to dark with no long intermission at any time is shown by the record. . . . The bird certainly deserves all the protection and encouragement that can be given it."

Joint report of the botanist and entomologist and the veterinarian on spermo-ophile or ground-squirrel investigations, C. V. PIPER and S. B. NELSON (*Washington Sta. Rpt. 1896, pp. 26-29*).—Brief statements are made concerning the life-history studies of the ground squirrel and experiments to exterminate it by poisons and by bacterial diseases.

AIR—WATER—SOILS.

Percolation, storage, and movement of water in the soil, P. P. DEHÉRAIN (*Ann. Agron., 24 (1898), No. 10, pp. 449-481, charts 4*).—An account is given of laboratory experiments with 200-gm. samples of soil to determine the difference in storage capacity, permeability, and capillary power of loose and compact soils. The results show that the loose soil is much more permeable and has a greater storage capacity for water than the compact soil. After prolonged rain, however, the capacity for water of the loose soil may gradually diminish until it becomes less than that of the compact soil at the beginning. Water percolates easily through loose soils, and thus a large reserve of moisture collects in the subsoil. On the other hand, water percolates slowly through compact soils, is subject to great loss by evaporation, and does not collect except in small quantities in the subsoil.

This subject was also investigated in vegetation boxes in which different crops were grown. The results confirm those obtained in the laboratory experiments. It was found that in the case of the loose soil a reserve of moisture collected in the subsoil within reach of the roots of plants, such as wheat and alfalfa. Water, however, rose by capillarity much more readily in the compact soil than in the loose soil.

The practical application of the facts demonstrated in these experiments is briefly discussed.

Percentage of water retained by long columns of sand, F. H. KING (*Wisconsin Sta. Rpt. 1897, pp. 254-256*).—Attention has been called in a previous report of the station (*E. S. R., 8, p. 297*) to the long-continued percolation of water from sands of different grades in cylinders 8 ft. long and 5 in. in diameter. Further observations on this subject are here reported. Tables show the amounts of water which percolated from the cylinders as measured at intervals, from February 7, 1894, to September 28, 1896, as well as the amount of water remaining in different sections (3 in.) of the columns at the latter date.

"These observations show very conclusively that the drying out of coarse, sandy subsoils may take place to so extreme a degree as to almost approach the so-called hygroscopic moisture dryness, no matter how perfect a mulch may be maintained over them, provided the interval between rains is long enough. They further show quite as conclusively that the coarse, sandy soils, no matter how inherently rich they may be in plant food, must remain unproductive in all localities where the ground water is not near the surface, unless good showers fall at short intervals or unless the rains are supplemented by irrigation."

The treatment of swamp or humus soils, F. H. KING (*Wisconsin Sta. Rpt. 1897, pp. 232-239, figs. 10*).—This is a continuation of previous experiments (E. S. R., 9, p. 536) on recently reclaimed swamp land. In the earlier experiments with corn little or no increase of yield was observed where commercial fertilizers had been applied, but there was a very decided improvement where barnyard manure had been used. Oats and barley following the corn derived decided benefit from the barnyard manure applied the previous year, but none from the commercial fertilizers so applied. Plats which had produced a uniformly good crop of corn in 1896 gave very irregular yields in 1897. Experiments were made in the plant house with soils taken from spots which had given good crops as well as from those on which the crops were poor. The pots used in these experiments were galvanized-iron cylinders 3 ft. in diameter and 4 ft. 4 in. deep, and held 2,200 lbs. of soil. Twenty-four of these pots were devoted to corn, 4 to oats, and 8 to clover, one-half in each case being filled with productive soil, the other with unproductive soil.

"In 4 of the cylinders planted to corn the soil was put in as loosely as possible, in order that it might be better aerated, while in all the others the soil was closely packed to imitate the field conditions. With 4 other cylinders cut, dry straw was worked into the surface 8 in. of the soil with a view to better aerating it by another method which might be presumed to imitate the conditions produced by the grass turned under with the first plowing of these fields, and also the mechanical effect of farmyard manure. Four other cylinders were given a dressing at the rate of 30.8 tons of farmyard manure per acre, both for better aeration and to supply new materials from which nitrates might be developed. Another 4 cylinders were given a dressing of sodium nitrate at the rate of 400 lbs. per acre, in order that available nitrates might be present to start with. Still another 4 were given potassium carbonate at the rate of 400 lbs. per acre, while the remaining 4, planted to corn, were given nothing and held as a check upon the first 4 which had the loose soil, these being filled with the firmed soil and presumably not so well aerated."

Three crops of corn in succession have been planted in these cylinders. In case of the first crop the yield was best on the manured cylinders. The yields on the cylinders receiving potash and cut straw stood next, the crop being equally benefited by these 2 materials. No benefit was derived from the nitrate applied. The yields were no better on the loosely packed soil than on the firmly packed soil.

"In the case of the second crop of corn the manured cylinders are decidedly ahead, while the cut straw, nitrate, and potash cylinders are about equally improved over the 2 sets of untreated cylinders, which again are about alike and show nothing gained or lost by the loose packing. . . .

"When the third crop came to be planted in July a very heavy crop of oats had been harvested from 4 oat cylinders, yielding over 12 tons of water-free matter per acre, and a good crop of clover had been taken from the clover cylinders. The 4 oat cylinders and 2 of those bearing clover were fitted for corn and planted with the others. . . .

"The corn on the oat stubble look decidedly as though it was nitrogen hungry, but the oats had an extremely dark-green look and seemed to be overfed with nitrogen rather than underfed. The clover made a good fair growth for the first crop, but it was not as large as the crop grown in the small cylinders on the upland soil, while the second crop was decidedly poor for some reason. But a good crop of corn followed the clover.

"This much seems clear in regard to the treatment of these black marsh soils, they respond well to farmyard manure, and even to coarse litter of any kind when well worked in, while the commercial chemical fertilizers tried, other than potash, have but little influence."

Fertilizer experiments with Indian corn on marsh soils, F. W. WOLL (*Wisconsin Sta. Rpt. 1897, pp. 264-271*).—This is an account of chemical investigations made in connection with experiments previously reported in part (E. S. R., 9, p. 536). In these experiments it was assumed that the marsh soil was abundantly supplied with nitrogen. For this reason the fertilizers used included only different forms of potash, phosphoric acid, and lime. The yield (grain and fodder) and the dry matter and nitrogen in the crops grown were determined, and the results are classified with reference to the degrees of fertility (poor, medium, and good) of the soil on which the crop was grown, as shown by chemical analysis.

While it is not considered safe to draw conclusions from results of one year's experiments, it is believed that the data obtained tend to show that the fertility of these soils "is in direct proportion to the content of potash, phosphoric acid, total nitrogen and active nitrogen (nitrogen soluble in water, expressed in parts per million), and in inverse proportion to the lime content of the soil."

The composition of the different grades of soil was as follows:

Composition of marsh soils from unfertilized plots.

Constituents.	Poor soil.		Medium soil.		Good soil.	
	First foot.	Second foot.	First foot.	Second foot.	First foot.	Second foot.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Insoluble matter.....	72.11	81.48	74.49	79.92	73.57	79.49
Volatile matter.....	12.30	4.82	11.35	5.80	11.73	4.38
Potassium oxid.....	.26	.35	.27	.34	.30	.34
Calcium oxid.....	1.44	1.49	1.35	1.21	1.05	1.32
Phosphoric acid.....	.18	.13	.20	.14	.22	.15
Nitrogen (total).....	.37	.05	.32	.10	.41	.12
Nitrogen soluble in water (parts per million).....	36.2	46.2	50.1

"The most plausible explanation of the different productive capacities of the poor, medium, and good soil lies, it would seem, in their different contents of active (nitric) nitrogen. For some reason or reasons as yet not understood, conditions in the poor soils have been unfavorable to the process of nitrification or favorable to denitrification. . . .

"The result of the investigation shows beyond a doubt that although some of the fertilizers applied did not appreciably increase the yield of fodder corn or ear corn, the quality of the product was in every case improved by the application of the fertilizers, both through the larger content of valuable food constituents in the corn and through the greater proportion of ears to stover in the crop from the fertilized plats."

Pot-culture tests of the productiveness of the soils of Minong pine barrens in Douglas County, Wisconsin, F. H. KING (*Wisconsin Sta. Rpt. 1897, pp. 249-253, fig. 1*).—There are "in the central and northern portions of Wisconsin large areas of very sandy soils which, if they ever become remunerative for agricultural purposes, must be made so through the application of special methods." Pot experiments with samples of such soils from Minong in Douglas County during 1895 and 1896 indicate that with irrigation combined with judicious fertilization good crops may be produced on soils of this character. The crop grown in these experiments was potatoes. The soils were irrigated once or twice each week during the season. The yield in the pots to which well rotted manure had been added was at the rate of 275.8 bu. in 1895 and 878.1 bu. in 1896. The water used by the crop was 16.39 in. in 1895, 29.51 in. in 1896.

For purposes of comparison similar experiments with potatoes were made on samples of local sands. The water used, including 4.48 in. of rainfall, was 20.05 in. in 1895. The yield on heavily manured soil (50 tons per acre) was at the rate of 605.5 bu. per acre; on soils receiving only 25 tons manure, 563.5 bu. In 1896 potatoes were again grown, without further manuring. The yields were 312 bu. per acre for the heavy watering (40.61 in. including rainfall) and light dressing of manure, and 344.5 bu. for the lighter watering (31.92 in.) and heavier dressing of manure.

Experiments of the above character were also made on the same sands and on good soil with clover in 1895 and barley in 1896. "While the crops produced on the sand have not been as large in all cases as those produced on the good soil, they have nevertheless been fair yields and nearly equal to those from the good soil when the sum of both crops is compared."

Results of studies of the higher atmosphere, G. HERMITE and C. BESANÇON (*Compt. Rend. Acad. Sci. Paris, 127 (1898), No. 16, pp. 574, 575, fig. 1*).—A small balloon was sent up August 23, 1898, to an altitude of about 7,305 meters. The balloon carried a barothermograph and a good automatic record of temperature and elevation was obtained. The minimum temperature recorded was -60° C. at about 6,500 meters.

Soil water, P. P. DEHÉRAIN (*Gard. Chron., 3. ser., 25 (1899), No. 630, p. 34*).—A scientific presentation in popular style of the principles governing the operations of tillage in their relation to control of soil moisture.

Studies on the surface tension of water in small capillary tubes, P. VOLKMANN (*Ann. Phys. u. Chem. [Wiedemann], n. ser., 64 (1898), No. 10, pp. 194-206*).

The farm water supply, F. W. MORSE (*New Hampshire Sta. Bul. 53, pp. 73-81*).—This bulletin discusses in a popular manner the character of the natural water supply in New Hampshire, the nature and causes of pollution, and the means of preventing contamination. The discussion is based upon analyses made at the station of numerous samples of well and spring water. It is shown that most of the natural waters of New Hampshire are very pure and soft. The unpolluted ground water contains as a rule less than 10 parts of solid matter dissolved in 100,000 parts of

water. Waters contaminated by drainage from the surface almost invariably contain a much larger solid residue and a higher proportion of chlorine than unpolluted water.

The conveyance of bacteria by underground water, E. PRUHL (*Ztschr. Hyg. u. Infectiouskrank.*, 1897, p. 549; *abs. in Jour. Soc. Chem. Ind.*, 17 (1898), No. 7, p. 687).—By means of pits dug to the water level in gravelly soil it was found that *Micrococcus prodigiosus* and fluorescent *Vibrio* were carried by the ground water through 8 meters (26.25 ft.) of soil in from 1 to 2 hours. "In further experiments the *prodigiosus* bacilli were found to pass into the supply of a tube well drawing its water through gravel for a distance of 3.7 meters (12.11 ft.) from the point where the cultures of bacteria were introduced into the water near the surface."

Studies on the composition of nitrate-bearing soil from the site of ancient Cairo, J. ZAMARON (*Bul. Assoc. Chim. Sucr. et Distill.*, 16 (1898), No. 6, pp. 553, 554).—Analyses of the soil from ancient rubbish heaps are reported, which show, among other things, an average of 2.19 per cent of nitric nitrogen, corresponding to 4.1 per cent of potassium nitrate.

On the influence of crops and manure on the nitrogen content of soils, C. F. A. TUXENS (*Landw. Vers. Stat.*, 50 (1898), No. 5-6, pp. 335-342).—For an abstract of this article as it appeared in another journal, see E. S. R., 10, p. 425.

On the pulverization of the soil, M. RINGELMANN (*Jour. Agr. Prat.*, 1898, II, No. 42, pp. 558-561, fig. 1).—A popular discussion of this subject.

Treatment of the soil; a question for the consideration of the farmers, W. G. WARING (*Tyrone, Pa.: Tyrone Times*, 1898, pp. 11).

The bringing of soil under culture, M. RINGELMANN (*Jour. Agr. Prat.*, 1899, I, No. 3, pp. 92, 93).—A brief, popular note on this subject.

On the cultivation of the soil, E. WOLLYNY (*Deut. Landw. Presse*, 25 (1898), No. 80, pp. 856, 857; 88, pp. 932, 933; 89, pp. 941, 942).—A discussion of the physical properties of soils in their relation to cultivation.

Drainage of the soil, S. GUÉRAND DE LAHARPE (*Jour. Agr. Prat.*, 1898, II, No. 50, pp. 846-849).—The advantages of drainage are discussed in a popular way.

The relative sensitiveness of plants to acidity in soil, W. MAXWELL (*Landw. Vers. Stat.*, 50 (1898), No. 5-6, pp. 325-330).—See E. S. R., 10, p. 128.

The inoculation of soils, A. HERTZOG (*Monatsber. Gesell. Förd. Wiss. Ackerbaues u. Künste Unter Elsass*, 32 (1898), No. 7, pp. 439-467).—Reports inoculation experiments with germ-containing soils and with pure cultures for nitrogen assimilation. Nitragin was successfully tested, and a trial of Alinit is contemplated.

Soil inoculation, TANCRÉ (*Landw. Wchnbl. Schleswig-Holstein*, 48 (1898), No. 17, pp. 290-293).

FERTILIZERS.

On the spreading and plowing under of barnyard manure, P. P. DEHÉRAIN (*Compt. Rend. Acad. Sci. Paris*, 127 (1898), No. 14, pp. 469-472; *Ann. Agron.*, 24 (1898), No. 9, pp. 401-416; *abs. in Rev. Sci.*, 4. ser., 10 (1898), No. 16, pp. 499, 500).—For the purpose of throwing light upon the losses of nitrogen which manure undergoes when placed in heaps in the field and allowed to remain some time before spreading, the author placed 10 gm. of manure in a wide glass tube and passed a current of air through it, determining the amounts of carbonic acid and ammonia in the gases which passed off. Of the 32 mg. of ammoniacal nitrogen originally present in the sample, 23.9 mg. passed off under this treatment in 2 days. The evolution of ammonia gradually decreased after this period, but at the end of 26 days 31.8 mg. of ammoniacal nitrogen had escaped. The evolution of carbon dioxide, however, continued quite uniform throughout the experiment, 590.4 mg. of this gas being obtained.

In another series of experiments 100 gm. lots of manure, either without covering or covered with a layer of soil 7 to 8 cm. thick, were subjected to currents of normal air or air to which ozone had been added. In this case the passage of 1,583 liters of air containing ozone removed 43.3 per cent of the ammoniacal nitrogen originally present, and the normal air 48.7 per cent. In the case of the manure covered with soil the amount of ammoniacal nitrogen removed by normal air was only 3.9 per cent. Analysis showed that a considerable quantity of organic nitrogen was also removed in the free state by this treatment. In the case of the air containing ozone 19.3 per cent of the original nitrogen was lost in a free state; in the case of the normal air 15.2 per cent.

The manure lost in both forms 26.4 per cent of its original nitrogen when subjected to the action of air containing ozone; 23.2 per cent with normal air when the manure was uncovered, and 22.7 per cent with normal air when the manure was covered with soil. When the manure and air were sterilized the loss of nitrogen was very small, showing that the evolution of ammonia and free nitrogen was due to the action of micro-organisms and not the result of purely chemical changes.

The fertilizer control for 1897, W. A. WITHERS (*North Carolina Sta. Bul. 151, pp. 113-122*).—Fertilizer inspection in North Carolina is now under the control of the State department of agriculture. The station is employed to make the analyses, but the collection of samples and the publication of results is in the hands of the commissioner of agriculture. This bulletin, therefore, is confined to a summary of the work of the year, including data relating to the increase in the number of brands of fertilizers, extent and distribution of the fertilizer trade, valuation of fertilizers, and average composition of fertilizers on sale in North Carolina during several years (1890-1897).

“The number of brands registered for sale in North Carolina during 1897 is about the same as for 1896, but before that year the number increased very rapidly for each year since 1890, when there was a change from the brand tax to the tonnage tax.” The number of brands offered for sale in the State in 1897 was 673 as against 666 the previous year. The consumption of fertilizers in the State has rapidly increased from year to year, amounting to about 208,000 tons, valued at about \$5,000,000, in 1897. “The larger part of the fertilizers now used in the State were manufactured in North Carolina and Virginia.”

The average composition of the principal classes of fertilizers used in the State during 1897 is shown in the following table:

Average composition of fertilizers sold in North Carolina in 1897.

	Available phosphoric acid.		Ammonia.		Potash.	
	Found.	Guaranteed.	Found.	Guaranteed.	Found.	Guaranteed.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Acid phosphates.....	12.96	12.15
Acid phosphates with potash.....	10.58	9.66	1.89	1.85
Ammoniated superphosphates with potash.....	9.01	8.01	2.85	2.56	2.43	2.15

The average composition of the fertilizers is about the same as in previous years except that there are slightly smaller percentages of ammonia and potash. "One out of every 4 of the usual fertilizers fell below the guaranty in some single ingredient and 1 out of 15 in its valuation."

Experiments on the action of phosphoric acid in bone meal and Valserine phosphate as compared with that of superphosphate and Thomas slag, P. LIECHTI (*Landw. Jahrb. Schweiz, 11 (1897), pp. 378-385*).—This is an account of comparative tests during 2 years (1896-1897) of the above phosphates on oats growing in galvanized-iron cylinders (20 cm. deep and 20 cm. in diameter) filled with a sandy humus soil containing a moderate supply of potash and phosphoric acid. The phosphatic materials used were bone ash superphosphate containing 16.3 per cent of water-soluble phosphoric acid in 1896 and 17.5 per cent in 1897; fine-ground Thomas slag containing 17.51 per cent total phosphoric acid and 15.68 per cent of citrate-soluble phosphoric acid, fine-ground Valserine phosphate containing 19.39 per cent total phosphoric acid and 1.44 per cent citrate-soluble phosphoric acid, raw bone meal containing 19.62 per cent total phosphoric acid and 4.32 per cent of nitrogen, fine-ground steamed bone meal containing 32.3 per cent phosphoric acid and 1.3 per cent nitrogen, and coarse steamed bone meal containing 32 per cent phosphoric acid and 1.4 per cent nitrogen. Each year phosphoric acid was applied in the different forms at the rate of 0.35 gm. per pot, or 111.46 kg. per hectare (99.3 lbs. per acre), together with supplementary applications of the necessary amounts of potash and nitrogen. The highest yields were obtained each year from the pots to which superphosphate and slag were applied. The pots receiving superphosphate yielded on the average in 1896 54.3 gm. of grain and 112.7 gm. of straw, containing 0.271 gm. of phosphoric acid; in 1897 the corresponding figures were 54, 83.3, and 0.2657. The pot receiving slag produced in 1896, 60.9 gm. of grain and 110.6 gm. of straw, containing 0.271 gm. of phosphoric acid; the corresponding figures in 1897 were 48.6, 76.1, and 0.292. It is thus seen that in case of the superphosphate and slag the yields were somewhat lower in 1897 than in 1896. There was a small relative increase in yield in the pots which had received insoluble phosphoric acid in the form of bone meal and mineral phosphate, but when the large amount of phosphoric acid actually applied in these cases is taken into account this increase is insignificant. The proportion of phosphoric acid applied which was recovered in the crops was as follows:

Proportion of phosphoric acid recovered in the crop.

	1896.	1897.
	<i>Per cent.</i>	<i>Per cent.</i>
Superphosphate.....	68	70
Thomas slag.....	68	73
Raw bone meal.....	0	0.04
Steamed bone meal (fine).....	3	2
Steamed bone meal (coarse).....	0	0

These results agree in general with those obtained by Wagner and Maercker; nevertheless the author concludes that such experiments do not furnish a reliable means of determining the relative value of different fertilizers.

How shall barnyard manure be managed, J. STOKLASA (*Wiener Landw. Ztg.*, 10 (1898), No. 40, p. 330; *abs. in Centbl. Agr. Chem.*, 28 (1898), No. 1, p. 62).—In the author's experiment decomposing liquid manure lost 50 per cent of its nitrogen in 30 days. This loss was not entirely prevented when the liquid was kept in deep pits unless these were hermetically sealed. From a test of various preservatives, including superphosphate and superphosphate gypsum, the author concludes that "bisulphate," a by-product from the manufacture of nitric acid, is the most effective and economical preservative material. Bisulphate contains 66 per cent of sulphuric acid in the form of acid sodium sulphate and frequently 2 per cent of potassium sulphate. Loss of nitrogen is completely prevented in manure treated with this substance to the extent of 0.5 per cent acidity. The liquid manure treated with this preservative must be applied to the soil alone. If mixed with the coarser manure a loss of nitrogen in the free state occurs.

Experiments on beets and barley with manure treated with superphosphate gypsum, A. OLSCHBAUER (*Deut. Landw. Presse*, 25 (1898), No. 66; *abs. in Centbl. Agr. Chem.*, 28 (1899), No. 1, p. 62).—The author concludes from his experiments that superphosphate is not as valuable as a manure preservative as is usually assumed. The best results were obtained by the author with manure preserved with street dirt.

Farmyard manure, G. E. DAY (*Ontario Agr. Col. and Expt. Farm Bul.* 109, pp. 24).—A popular discussion of this subject, based partly upon results of investigations at the experimental farm. The topics treated are constituents of plants, farmyard manure, solid and liquid excrements, influences which affect the composition of manure, care of farmyard manure, application of farmyard manure, and valuation of fertilizing constituents in manure.

Manures and composts, H. BOIRET (*Fumiers et composts. Annecy: Hérisson & Co.*, 1898, pp. 24).

Fertilizer inspection, C. D. WOODS (*Maine Sta. Bul.* 45, pp. 24).—The results of analyses of 199 samples of commercial fertilizers are reported. The bulletin also includes a comparison of guarantees and analyses of samples collected by the station for 3 years, the chief provisions of the State fertilizer law, and a list of manufacturers complying with the law in 1898.

"A comparison of the results of the analyses of the samples collected by the station, with the percentages guaranteed by the manufacturers, shows that, as a rule, the fertilizers sold in the State are well up to the guaranty."

Commercial fertilizers, M. A. SCOVELL, A. M. PETER, and H. E. CURTIS (*Kentucky Sta. Bul.* 76, pp. 97-105).—This bulletin calls attention to the main features of the State fertilizer law, gives directions for sampling fertilizers, discusses briefly the selection of fertilizers for different crops, and reports analyses of 48 samples of fertilizing materials.

Fertilizer analyses, R. C. KEDZIE (*Michigan Sta. Bul.* 161, pp. 441-456).—This bulletin gives an abstract of the State fertilizer law, with an explanation of its objects; a schedule of commercial prices, with notes on the valuation of fertilizers; an explanation of terms used in fertilizer analyses; a brief discussion of the principles underlying the use of fertilizers and of the sources from which nitrogen, phosphoric acid, and potash in fertilizers are derived, and tabulated valuations and analyses of 61 samples of fertilizing materials inspected during 1898.

Analyses of commercial fertilizers, H. J. WHEELER and B. L. HARTWELL (*Rhode Island Sta. Bul.* 48, pp. 13-34).—This bulletin deals with changes in the regulations regarding the inspection of fertilizers and cooperation in the work of fertilizer

inspection, and gives a schedule of trade values of fertilizing materials, text of the Rhode Island fertilizer law as amended March 1, 1898, a list of licensed fertilizers sampled by the chemist of the Rhode Island State Board of Agriculture, and analyses and valuation of 121 samples of fertilizing materials.

"In May, 1897, the fertilizer law which had been in operation in the State since April, 1892, was amended in such a way that the State Board of Agriculture, under whose authority the inspection had nominally been conducted, was released from any obligation to cause the work of the inspection to be done at the Rhode Island Agricultural Experiment Station, as heretofore."

This change did not prove satisfactory, and in March, 1898, the law was again amended so that the inspection of fertilizers was placed in the hands of the board of managers of the Rhode Island College of Agriculture and Mechanic Arts.

Analysis of licensed commercial fertilizers, F. W. WOLL (*Wisconsin Sta. Rpt.*, 1897, pp. 257-263).—Notes on the commercial forms of the 3 essential elements of plant food and on valuation and tabulated analyses and valuations of 14 samples of fertilizers licensed in Wisconsin in 1897.

The different forms of lime for fertilizing purposes and their value and use, F. WAGNER (*Vrtljschr. Bayer. Landw. Rath.*, 3 (1898), No. 1, pp. 1-20).—The different forms and sources of lime fertilizers are described with reference to Bavarian conditions.

Lime, nitrogen, and soda, H. J. WHEELER (*Rhode Island Sta. Bul.*, 47, pp. 10).—A brief summary of the results of investigations by the station (E. S. R., 9, pp. 933, 935) on the use of lime, the relative crop-producing power of different forms of nitrogen on acid soils, and on soda as a substitute for potash.

The basis of the selling price of phosphatic slags, J. GRAFTIAU (*Bul. Assoc. Belge Chim.*, 12 (1898), No. 9, pp. 328-331).—Discusses fineness and citrate-solubility as bases of valuation.

The drying of superphosphates, A. PETERMANN (*Jour. Soc. Agr. Brabant-Hainaut*, 1898, No. 25).

The production and utilization of natural nitrates in agriculture, V. AYMÉ (*Rev. Sci. [Paris]*, 4. ser., 10 (1898), No. 26, p. 817).—A general discussion of this subject.

Nitrogenous fertilizers—nitrate of soda and sulphate of ammonia, L. GRANDEAU (*Jour. Soc. Agr. Brabant-Hainaut*, 1898, No. 20).

Statistics of production and consumption of nitrate of soda, MAIZIÈRES (*L'Engrais*, 14 (1899), No. 2, pp. 35-37).—The exports and consumption for a number of years past are stated. The exports from Chile in 1898 are stated to be 1,260,000 tons. Of this 140,000 tons was consumed in America and 1,040,000 tons in Europe.

FIELD CROPS.

Report of the department of agriculture (*Washington Sta. Rpt.*, 1896, pp. 5-26).—The results of experiments with wheat, oats, corn, and forage plants, and in seeding pastures and permanent meadows are reported, and the work of the department is briefly described.

The experiments with wheat comprised variety tests, trials of different depths of plowing, and different rates and methods of seeding. Seventy-six varieties of winter wheat and 24 of spring wheat were tested. The following varieties of winter wheat, in the order given, averaged best for the seasons of 1895 and 1896: White Track, White Blue Stem, Seneca Chief, Thiess, Tasmania Red, Turkey, German Emperor, and Valley. The results of plowing at different depths showed that the yield increased with the depth up to 6 in., while beyond

the yield was materially reduced. In the seeding test the wheat was sown at rates varying from 2 to 5 pk. per acre. The largest yield was obtained from sowing 2 pk. per acre, the next largest from sowing 4½ and 5 pk., and the smallest from sowing 2½ pk. Drilling gave better results than broadcasting.

Plowing 6 in. deep for oats gave better results than plowing either 3 or 9 in. deep. Harrowing the soil 4 times before seeding instead of only once increased the yield per acre by 6 bu. On 9 plats oats were sown broadcast on the stubble and covered by means of a disk harrow, and then 3 of the plats were dragged twice and 3 dragged once and rolled. The results gave a difference of about 3 bu. per acre in favor of harrowing or harrowing and rolling. Of 13 varieties White Russian produced the best average yield for 1895 and 1896.

Twelve varieties of corn were tested to ascertain which kind reached the most advanced stage before frost. White dent gave the best results, reaching the proper stage for cutting before frost and yielding about 10 tons of silage per acre.

The grasses and forage plants grown at the station on experimental plats, permanent meadows, and in pastures are enumerated and a number of them briefly discussed.

Fiber flax investigations, F. A. HUNTLEY (*Washington Sta. Bul.* 33, pp. 21, figs. 1, pl. 1).—This bulletin reports culture and variety tests and retting experiments with flax, and describes in a popular way the various operations which enter into its culture and the preparation of the fiber. The results of the culture and variety tests are given in the following table:

Yield of flax from different varieties of seed.

	Variety of seed.	When sown.	Amount sown per acre.	Character of soil.	Yield of un-threshed straw per acre.	Yield of threshed straw per acre.	Yield of seed per acre.
			<i>Pounds.</i>		<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>

Plat 13	do	do	120	do	4,080	2,800	569

Retting was performed by submerging the straw placed in crates in a slow-flowing, clear stream, by anchoring the straw tied into bundles in a pool filled with water from the same stream and by placing it in special retting tanks. The water in the stream and pool maintained a temperature of about 51° F. and the retting required an average duration

of 14 days. In the retting tanks the temperature of the water was kept at 100° during the day and raised to 110° in the evening and allowed to fall from 5° to 15° during the night. These ranges of temperature produced the best results and the retting was usually completed in 110 hours. A higher temperature did not hasten the process and an average temperature of 20° lower prolonged it to about 145 hours. At 150° no retting took place.

A report on the culture of hemp in Europe (*U. S. Dept. Agr., Office of Fiber Investigations Rpt. 11, pp. 29, figs. 6*).—This includes a special consular report on the growth of hemp in Italy. The author reviews the hemp industry in this country and in France, discusses the kind of hemp grown in different countries, and gives directions for the various operations which enter into the culture of hemp and its preparation for market. Notes are given on the cultivation, drying, and cleaning of hemp in Italy.

The consular report discusses Italian hemp culture, describes the hemp plant, reports its chemical composition as determined by several authorities, and gives full directions for its culture and preparation. A plan of crop rotation is given in which the farm is divided into 18 fields and each year 6 fields grow alfalfa, 6 wheat, and 6 hemp. Notes are given on the construction of retting pools.

The influence of soil moisture and fertility on the development of the oat plant, M. TUCKER and O. VON SEELHORST (*Jour. Landw., 46 (1898), No. 1, pp. 53-63*).—These investigations on the development of the different parts of the oat plant were carried on as pot experiments. The pots were 33 cm. high and 24 cm. in diameter, and thus gave considerable space for root development. Each pot contained 17,130 gm. of dry soil and 712 plants were grown. The pots were divided into 3 series, according to the amount of moisture in the soil. At the beginning of the experiment, March 29, the amount of water furnished the soil was as follows: First series, 14.35 per cent; second series, 15.41 per cent; third series, 16.44 per cent, being 41.6, 45.2, and 48.8 per cent, respectively, of the water-holding capacity of the soil. May 18 the moisture was increased to 47.4 per cent of saturation in the second series and 53.2 per cent in the third, and on June 4, when the plants were heading, it was further increased in these series to 51.7 and 63.7 per cent of saturation, respectively. About 1 week later the water content in these series was increased to 56.1 and 70.6 per cent of saturation, respectively. Potash was applied in the form of potassium carbonate, phosphoric acid in the form of monocalcic phosphate, and nitrogen in the form of sodium nitrate in amounts shown in the table, which also summarizes the results.

Effects of different amounts of soil moisture and fertilizers on the development of the oat plant.

Most of the plants were ripe August 9, but the plants grown in pots which received no fertilizer and those which received only potash and nitrogen were not ripe until August 16. In general the increase in soil moisture increased the development of the parts of the plant above ground and decreased the development of the roots. The fact that the soil with the lowest moisture content favored root development is considered due to hydrotropism. The plants which received no phosphoric acid showed the least root development and gave the smallest yields. The authors conclude that increase in soil moisture diminishes root development and that fertilizing increases it, but that these 2 factors acting in conjunction increase the yield.

Experiments with oats, J. F. DUGGAR (*Alabama Sta. Bul. 95, pp. 157-180*).—The experiments with oats here reported consisted of variety and fertilizer tests and investigations on the time of sowing, rotations, and the prevention of smut.

Five varieties of oats imported from France were compared with varieties obtained from seedsmen and Red Rust Proof oats grown at the station. All varieties except one were sown at the rate of 44 lbs. per acre on November 16, 1896, and all plats were $\frac{1}{11}$ of an acre in size. The foreign varieties were evidently spring oats, and only one, Gray Winter, proved hardy and has for 2 years ranked well among the varieties tested. Virginia Gray and Red Rust Proof, both American varieties, produced the best yields of grain. Seed from the varieties tested in 1896 and of a few additional varieties was sown November 6, 1897. In the same field spring and fall strains of Red Rust Proof oats were tested. Red Rust Proof, Beardless, Hatchett Black, and Gray Winter, in the order given, produced the most grain. Red Rust Proof yielded 30.8 and Gray Winter 19.5. There was practically no difference between the spring and fall strains of Red Rust Proof oats, which

is considered due to a mild winter. Of 7 varieties sown February 17, 1898, Burt, May, and Red Rust Proof were most productive, yielding 41.4, 35.9, and 30.6 bu. per acre, respectively. The yield of Red Rust Proof is the average of 2 plats. The varieties grown as Burt and May appeared to be identical. The winter varieties, Virginia Gray, Meyer Turf, Black Belgian Winter, and Black Mesdag, failed. The Black Belgian Winter oats produced no grain at all. In the experience of the station Red Rust Proof is the only general purpose variety for that locality, although Meyer Turf, Virginia Gray, Delaware Winter, and Gray Winter were found to be hardier. Burt ripened 1 to 2 weeks before Red Rust Proof sown on the same date in the spring and only 1 to 3 days later when this variety was sown in the fall. Red Rust Proof matured 12 to 19 days earlier when sown in November than when sown in February. Meyer Turf, Virginia Gray, and Gray Winter matured 10 to 12 days later than Red Rust Proof, and Hatchett Black matured between Red Rust Proof and Meyer Turf.

Three experiments were made on fall and spring sowings with Red Rust Proof oats, the average results showed that oats sown in November yielded 9.8 bu. of grain and 531 lbs. of straw per acre more than oats sown in February and March. The average date of harvesting the spring-sown crop was June 12, and of the fall-sown crop May 26.

Oats grown after cowpeas, the vines having been plowed under, produced 10.4 bu. of grain and 229 lbs. of straw per acre more than oats grown after German millet plowed under as a fertilizer. On a series of 6 plats velvet bean vines, velvet bean stubble, cowpea vines, cowpea stubble, crab grass and weeds, and German millet stubble were plowed under. The plats were then fertilized with 220 lbs. per acre of acid phosphate and 44 lbs. muriate of potash and sown to oats in the fall. The average yield of oats per acre was 33.6 bu. after velvet beans, 31.6 bu. after cowpeas, and 8.4 bu. after crab grass and weeds and German millet. There was a gain of 24.2 bu. of oats and nearly $\frac{3}{4}$ of a ton of straw per acre as a result of growing leguminous instead of nonleguminous crops during the preceding season. The plats on which the velvet bean and cowpea stubble had been plowed under produced better yields than those on which the vines were plowed under. This is believed to be due to the fact that the vines were not properly buried by the plow and that the stubble ground made a better seed bed. Three series of experiments, 2 with fall-sown oats, and 1 with spring oats were made to determine the best time of applying nitrate of soda as a top-dressing. In all cases the application was more effective when applied in March than when used in the latter part of April.

Four plats were sown to oats after having been fertilized with complete fertilizer and 2 of the plats received in addition 660 lbs. slaked lime per acre. There was a difference of 12.9 bu. per acre in the yields in favor of the limed plats. One thousand pounds of quicklime per acre, applied as a top-dressing after being slaked, effected no gain on

poor sandy soil. A cooperative fertilizer experiment with oats sown in February failed on account of dry weather. The plats receiving kainit offered the greatest resistance to the drought and produced the largest yields.

Equal quantities of seed oats by weight were sown on 2 plats of poor sandy soil. The seed for 1 plat had been scalded in water at 130 to 135° F. for 10 minutes. The untreated seed yielded 13.1 bu. and the treated seed 14.2 bu. per acre. The heads on both plats were counted and it was found that on the plat with untreated seed 5.9 per cent of the heads were destroyed by smut and no smut was found on the other plat. Complete directions are given for the Jensen or hot-water treatment for the prevention of smut.

The influence of depth of planting on growth and productiveness of potatoes, E. S. GOFF (*Wisconsin Sta. Rpt. 1897, pp. 306, 307*).—An experiment was conducted to determine the influence of depth of planting on productiveness, size, and manner of growth of potatoes. Twenty-five hills of Burbank potatoes were planted May 22, at different depths. The seed tubers were planted whole, one in a place, 2 ft. apart, in rows 3½ ft. apart. Ordinary cultivation was given, and the crop was harvested October 13 to 14. The results obtained are given in the following table:

Results of planting potatoes at different depths.

Depth planted.	Hills germinating.	Tubers protruding from soil.	Average number of tubers per hill.	Average weight of tubers per hill.	Average depth to deepest tubers.
	<i>Per cent.</i>	<i>Per cent.</i>		<i>Pound.</i>	<i>Inches.</i>
2 inches	100	8.4	6.6	0.58	2½
4 inches	96	.8	5.4	.62	3½
6 inches	88	.0	3.2	.35	5

Growing rye after potatoes, M. FISCHER (*Fühling's Landw. Ztg., 47 (1898), No. 18, pp. 702-706*).—It is stated that rye grown after potatoes frequently gives an unsatisfactory yield, which is believed to be due to the fact that a hoed crop like potatoes leaves the soil too loose for the rye plant. To ascertain whether this belief is correct rye was grown on 10 plats on which fertilizer experiments with potatoes had been made the previous year. Two of these plats were fertilized with nitrate of soda, 2 with lime, 3 with barnyard manure, 1 with Thomas slag, and 2 receiving no fertilizer. The best yields were obtained from the plats which were fertilized with nitrate of soda. From the results obtained it is concluded that the mechanical condition of the soil is not the direct cause of the unsatisfactory yields of rye when grown after potatoes, but that the potato, especially when it remains in a growing condition nearly to the time of harvesting, uses most of the available nitrogen and leaves an insufficient supply to enable the rye to make a good growth.

The growth and use of the rape crop, J. A. CRAIG (*Wisconsin Sta. Rpt. 1897*, pp. 56-71, figs. 3).—This article gives complete and detailed instructions for the culture and use of the rape crop and reports the results of cutting rape for soiling purposes. The limits to the growth and use of rape are pointed out, the different varieties described, and directions given for the seeding, cultivation, and use of the crop.

A half-acre plat of rape was used for soiling purposes and furnished feed for one month beginning August 16. The rape was cut close to the ground and owing to the lateness of the season did not make a heavy second growth. A number of trials were made with different methods of cutting and twisting the plants. Results are given in the following table:

Results of different methods of twisting and cutting rape.

Method of treatment.	Yield.			Total.
	Aug. 29.	Sept. 29.	Nov. 8.	
	Pounds.	Pounds.	Pounds.	
Five rows twisted 8 in. from ground.....	253	157½	159½	569½
Five rows cut 8 in. from ground.....	273	206½	153½	633
Five rows cut 4 in. from ground.....	293	Not cut.	431½	724½
Five rows cut close to ground.....	343	Not cut.	296	639

In this test cutting rape 4 in. from the ground gave the best results. Cultivation immediately after each cutting is recommended.

Another experiment was made to determine the best time for cutting the crop. The following results were obtained:

Results of cutting rape at different times.

	First cutting.		Second cutting.		Third cutting.		Total.
	Date.	Yield.	Date.	Yield.	Date.	Yield.	
		Pounds.		Pounds.		Pounds.	
Plat 1.....	June 25-July 1	3,062	Aug. 6-12	2,389½	Oct. 22-28.....	2,218	7,669½
Plat 2.....	July 2-8.....	4,081½	Aug. 13-19	1,708	Oct. 29-Nov. 4.	1,987	7,776½
Plat 3.....	July 9-15.....	2,939	Aug. 20-26	1,443	Too light for cutting.		4,382

The author concludes that rape sown as early as possible, cut 4 in. from the ground, and cultivated frequently, will furnish 3 cuttings during the summer and fall.

Special report on the beet-sugar industry in the United States, 1897 (*U. S. Dept. Agr., Special Report on the Beet-sugar Industry in the U. S., 1897*, pp. 210, figs. 2, maps 2).—This publication is a comprehensive report of the conditions of sugar-beet culture and beet-sugar manufacture in the United States in 1897. The results of analytical and experimental work, and statistics concerning the production of beet sugar and the cost of producing sugar beets are given.

Report of the chemist, H. W. Wiley (pp. 1-160).—This report gives a bibliography of Department publications on the sugar-beet industry, reviews in general the work of the Department and the experiment stations with sugar beets, and reports the results of analyses made in the chemical laboratory of the Department and at different experiment stations. The climatic conditions are considered in general and the probable areas suited to beet culture are shown on a map. The average rainfall for the months of April to October, inclusive, at different places in 11 States east of the Mississippi are tabulated, and the conditions of temperature and precipitation of particular localities throughout the country are noted. The following table gives the results of analyses of beets for States from which 10 or more samples were obtained:

Composition of sugar beets grown in different States, 1897.

State.	Number of samples.	Number of counties represented.	Average results.			Maxima.		Minima.	
			Weight.	Sugar in the beet.	Purity coefficient.	Sugar in the beet.	Purity coefficient.	Sugar in the beet.	Purity coefficient.
Colorado	174	26	20	13.6	76.7	20.9	88.1	4.1	63.4
Illinois	32	19	17	13.1	75.5	21.2	86.8	8.3	67.7

Tennessee	17	5	11	10.8	71.9	14.9	74.1	5.6	69.8
Texas	11	8	22	12.6	76.5	14.7	80.1	8.8	72.3
Utah	35	7	20	14.3	81.1	20.2	90.5	9.1	70.6
Virginia	34	21	21	11.6	76.2	15.5	83.3	5.6	65.4
Washington	34	10	27	13.7	80.7	19.9	89.7	5.8	67.0
West Virginia	14	5	19	15.4	80.4	18.9	88.8	11.9	69.1
Wisconsin	42	8	15	15.8	83.3	19.5	88.2	11.5	71.4
Wyoming	34	9	19	17.2	82.3	24.3	92.1	9.1	70.2

The analytical data presented in the table are elucidated by a brief discussion of them for each State, supplemented by a summary of the results obtained by the experiment stations in the different States. Suggestions based on some of the data obtained are made on the influence of temperature on the quality of sugar beets, and in this connection the significance of the theoretical thermal belt suitable to the growing of sugar beets is pointed out. The use of sugar beets and beet pulp as cattle feed is discussed, with a review of feeding experiments in this line, and the results of analyses of diffusion pulp are quoted. Data collected in previous years from cultural tests of sugar beets in various States are summarized in tables.

The investigations in seed production carried on under the direction of the Department of Agriculture at the New York State, Indiana, Wisconsin, Iowa, Kentucky, and Tennessee stations are described for each

station. A number of varieties of high-grade beets were grown at each station and analyzed, and samples were also sent to the Department laboratory for analysis. The most satisfactory results were obtained at the New York State Station. The classification of the beets of each variety based on the sugar content is given in the following table:

Classification of sugar beets of different varieties grown at the New York Station at Geneva.

Variety.	Number of beets having contents of sugar from—				Maximum polarizations of individual beets.	Minimum polarizations of individual beets.
	15 to 16 per cent.	16 to 17 per cent.	17 to 18 per cent.	18 per cent and above.

The work of the experiment stations reviewed in this publication has been abstracted from the bulletins of the respective stations.

Report of the special agent, C. F. Saylor (pp. 161-240).—This is a comprehensive presentation of the conditions of the sugar-beet industry in the United States in 1897, the methods in vogue to aid its growth, and the natural resources and commercial advantages and opportunities which exist and tend to make it a profitable field for labor and capital. The author discusses in a popular way the experiments in growing sugar beets in 1897, the region adapted to the culture of the sugar beet, and the factory requirements with reference to the quality of the beets and the materials used in the manufacture of beet sugar. General suggestions are given on the various operations connected with the growing of sugar beets, and statistics are presented on the consumption of sugar in the United States and leading European countries and the beet-sugar industry in Germany for the years 1892 to 1895. The experiences and observations of factory officials and operators and successful sugar-beet growers, obtained through a series of questions concerning their work, are reported. The cost of growing sugar beets and the cost and running expenses of factories are estimated in detail. Notes are given on the by-products of beet-sugar manufacture.

A soil study of sugar beets, W. P. HEADDEN (*Colorado Sta. Bul.* 46, pp. 63).—This bulletin presents the results of a study of the effects of alkali on the composition of the sugar beet. The experiments were made to determine the effects of the accumulation of various salts on or near the surface of low or poorly drained lands under irrigation. The soil on which they were conducted varies from a gravelly loam to a fine alluvium with a calcareous subsoil, being very retentive of water

to a depth of $5\frac{1}{2}$ ft., where it is underlaid by a stratum of clay practically impervious to the water which fills the gravel below. The salts mentioned as present in the soil are sodium chlorid, sodium carbonate, sodium sulphate, magnesium sulphate, and calcium sulphate. Check plats were located on good soil presumably free from alkali.

After irrigation or other favorable conditions incrustations of soluble salts $\frac{1}{2}$ in. in thickness formed on the surface of portions of the plat on which the sugar beets were grown. The ground was plowed and subsoiled to a depth of 14 in., and the seeds were drilled in rows 2 ft. apart. From the analyses of the beets produced the author concludes that the effect of the alkali upon the sugar content was not detrimental. Beets were analyzed each week, from September 2 to October 13, to test the increase in sugar content during the ripening period. The most marked increase was found to have occurred from October 6 to 13. "This change which we speak of as the maturing of the beets makes a difference of from 2 to 3 per cent." Beets left in the ground and protected against severe freezing did not show a loss in sugar or in weight.

Analyses were made to determine the distribution of sugar in the beets and the effects of freezing and drying. It was found that the difference in the average percentage of sugar in the thirds of beets, taken by weight, was less than 2 per cent in favor of the middle and lower thirds, but the coefficient of purity was practically the same throughout. The percentage of sugar in the crown was about 1 per cent less than in the rest of the beet, while the coefficient of purity was but little lower. Freezing without subsequent thawing did not seem to affect the quality of the beet, while drying increased the percentage of sugar, but was accompanied by an actual loss of sugar. The loss in drying amounted to about 5 per cent during the first 24 hours, but it fell to about 2 per cent at the end of 5 days, and then remained practically constant for the next 12.

It was shown in these experiments that the weight of the leaves was equal to about 87 per cent of the weight of the roots. The weight of the leaves did not increase materially during the last 6 weeks of the growing season, but the weight of the root increased by 64 per cent of its weight at the beginning of the period, September 2, or 39 per cent of the weight of the mature beet. The presence of alkali slightly increased the weight of the leaves but had no marked influence on the maturing of the crop. From the results of numerous analyses of the beets, which are given in tables, it was found that the presence of alkali had had no influence on the amount of dry matter, and that the dry matter other than sugar decreased as the formation of sugar in the beet progressed. The dry matter of the upper third of the beet was a little higher than in the other two-thirds.

As shown by the ordinary fodder analysis, the presence of alkali increases the percentage of ash and crude protein and decreases the percentage of nitrogen-free extract. The alkali had a greater effect upon the composition of the beet than upon that of the leaves. The

mature beet as grown in these experiments contained about 1.1 per cent of ash and the leaves a little more than twice as much. The effect of alkali was to increase the percentage of ash in the roots by about 2 per cent of the dry matter. The upper third of the beets was found to contain a higher percentage of dry matter than the other two-thirds, but the dry matter of the lower third was richer in ash than that of either of the other two. The author states that he failed to find any relation between the percentage of sugar and the percentage or composition of the ash.

The character of the soil did not seem to affect the composition of the ash which is believed to be very constant: the analyses show the following approximate percentages: Sulphuric acid, 3.5; phosphoric acid, 7 to 9; alkalis, 48 to 52; lime, 2 to 3; magnesia, 6; chlorine, 11.50 to 14.50; carbon dioxide, about 15. The ash of the leaves contained from one-third to one-fourth as much phosphoric acid, from 2 to 3 times as much chlorine, a little more lime, about one half more magnesia, and about $\frac{1}{13}$ less alkalis than the ash of the roots.

Four series of tests were made to determine the effect of some of the salts found in the soil on the germination of different varieties of beet seed. The salts were used separately and in conjunction, in quantities varying from 0.01 to 1 per cent of the air-dried soil in which the seed was germinated. The first series of tests was made with sodium carbonate, the second with sodium sulphate, the third with a mixture of these two, and a fourth with magnesium sulphate. Seeds were germinated in ordinary glass tumblers. It was found that the beet seed germinated freely in soil containing 0.1 per cent of sodium carbonate, but the young plants were injured in soil containing only 0.05 per cent. The influence of sodium sulphate was less marked, but it proved injurious when present in larger quantities than 0.8 per cent of the air-dried soil. When both of these salts were present in equal quantities, the action of the carbonate was not influenced perceptibly. One per cent of magnesium sulphate retarded germination, and the presence of sodium salts hastened it. Of the varieties tested in these experiments Vilmorin seemed to be most sensitive to the action of the alkali.

New Mexico sugar beets, 1897, A. GOSS (*New Mexico Sta. Bul.* 26, pp. 71-113, pl. 4).—This bulletin presents the results of culture experiments with sugar beets, carried on at the station and in 14 of the 18 counties of the Territory. Popular directions are given for the various operations in sugar-beet culture, including irrigation, and statistics concerning the sugar industry are tabulated.

The average results at the station with different varieties of beets harvested at different dates were as follows: Beets harvested September 15 averaged 1.22 lbs. in weight, 11.03 per cent sugar in the juice, and 78.8 in purity; beets harvested October 14, 1.53 lbs. in weight, 12.47 per cent sugar in the juice, and 79.4 purity; and the beets harvested November 16, 1.71 lbs. in weight, 13.89 per cent sugar in the juice, and 77.2 purity.

The beets in the samples from the 14 counties averaged 1.83 lbs. in weight, 14.46 and 13.74 per cent sugar in the juice and the beet, respectively, and 77.9 in purity. Fourteen samples from San Juan County gave an average of 16.46 per cent of sugar in the juice and 81.3 purity, the beets averaging 2 lbs. in weight. The samples from Taos County showed an average sugar content in the juice of 17.42, a purity of 80.7, and an average weight per beet of 1.17 lbs.

On a series of plats at the station beets were harvested and analyzed each month from September to March, inclusive. "The beets did not attain their full sugar content until the middle of November, and . . . The sugar content remained practically constant from that time until the middle of February. In March the sugar had begun to decrease, due, doubtless, to the fact that the beets had started to grow."

Analyses were made of beets varying in weight from $\frac{1}{4}$ to $9\frac{3}{4}$ lbs. It was found in general that the sugar content and the purity decreased as the size of the beets increased, ranging from 16.2 per cent sugar and 82.2 purity in the $\frac{1}{4}$ -lb. beets to 8.8 per cent sugar and 66.2 purity in the $9\frac{3}{4}$ -lb. beets.

Fifty well-formed beets, dug November 18, were divided into 5 equal lots, kept at an ordinary room temperature and analyzed at different periods, to study the effect of drying. The results are given in the following table:

Sugar content and purity of sugar beets as affected by drying.

Analyzed after harvesting.	Average weight per beet in fresh sample.	Sugar in juice.	Purity.	Decrease in water content.	Increase in sugar content.
	<i>Pounds.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
0 days.....	1.44	14.3	84.1	0.	0.
6 days.....	1.56	15.9	79.9	9.0	11.2
15 days.....	1.52	18.5	81.1	21.7	22.7
21 days.....	1.51	20.0	82.3	25.9	28.5
28 days.....	1.46	21.5	81.8	33.7	33.5

It is stated that 15 tons of sugar beets per acre remove from the land 105 lbs. of potash, 30 lbs. of phosphoric acid, and 60 lbs. of nitrogen; and that 30 bushels of wheat per acre remove in the grain and straw 28 lbs. of potash, 23 lbs. of phosphoric acid, and 45 lbs. of nitrogen.

The importance of the right amount and the right distribution of water in crop production, F. H. KING (*Wisconsin Sta. Rpt. 1897, pp. 216-231, figs. 9*).—Experiments with supplemental irrigation at the station during 3 years have shown that as a rule the natural supply of water (rainfall) is not sufficient for the maximum yields of the ordinary farm crops. This article summarizes the results of experiments along this line on barley followed by clover, potatoes, and corn.

Barley.—In the experiments with barley in 1897, the rainfall of 5.81 in. was supplemented by 4.16 in. of irrigation water (2.32 in. applied June 17 and 1.84 in. applied July 9). The results indicate that the

amount and distribution of rainfall during this season was such as to give nearly the maximum yield of barley; so that there was little difference between the yields on the irrigated and unirrigated plats. The clover following the barley, however, was decidedly benefited by irrigation. This crop received 3 additional irrigations (July 23, August 20, and September 8), amounting in the aggregate to 12.84 in.

The result of these 3 irrigations was a second crop of barley and clover mixed, which was cut and put into the silo September 22, weighing 6,552 lbs., from 25,330 sq. ft., or 1.36 tons of hay per acre, containing 15 per cent of water. With the rainfall of this year this crop would have been nothing, and there would have been a much poorer stand of clover.

Clover.—The rainfall during the season of growth of the clover was 9.44 in. This was supplemented by 5.85 in. of irrigation water, divided between May 18, June 1, July 7, and July 22, making the total amount of water which the clover crop received 15.29 in. The total yield of hay in 1897 was 4.43 tons, the second crop being 1.8 tons. “It is safe to say that with plenty of water, either as rain or irrigation, both the first and second crops of hay may easily be made double what is usually realized.”

Potatoes.—In these experiments Rural New Yorker potatoes were planted in rows 30 in. apart, with hills 15 in. apart, and Burbank potatoes were planted 30 in. apart both ways. Alternate groups of 6 rows were irrigated in each case, the Rural New Yorkers receiving 8.25 in. of water July 20, 21, August 19, and September 8; the Burbanks 6.79 in. on the same dates, making, with the rainfall of 11.49 in., 19.74 and 18.28 in. respectively of total water. The gain due to irrigation was 126.2 bu. per acre in case of the Rural New Yorker and 117.1 bu. in the case of the Burbanks. The results also show that water applied to one side of the row (half irrigation) “does not produce the maximum results, the mean loss by half irrigation being for the 2 years and 4 sets of trials 70.3 bu. of merchantable potatoes per acre, while the mean gain for full irrigation over no irrigation was 105.8 bu. per acre. “In the case of the rows of potatoes next to the half irrigated ones the mean yield was increased by the watering 7.9 bu. per acre. It is plain, therefore, from these two years’ work that plenty of water at the right time is indispensable to the largest yields of potatoes.”

It was observed that tip burn did less injury on the irrigated plats than on those which were not irrigated.

Corn.—Plats which have not been fertilized since 1894 have been planted continuously from 1894 to 1897, one-half in flint corn, the other half in dent corn. The rainfall, which ranged from 4.48 in. in 1895 to 15.02 in. in 1896, was supplemented by irrigation water amounting to from 5.7 in. in 1897 to 26.6 in. in 1895. The yield was invariably increased by the supplemental irrigation, showing that in none of these years were the amount and distribution of rainfall such as to produce the maximum yield of corn. In these experiments the effect of the rate

of planting was also studied. Corn was planted in rows 4 in. apart and in hills 15 in. apart at rates of 4, 3, 2, and 1 stalk to the hill.

"The maximum yield of feed per acre was secured with 3 stalks in a hill when the natural rainfall fed the crop, and also when this was supplemented with a little more than 7 in. of water by irrigation. So, too, the smallest yield of dry matter per acre was secured in every one of the 4 cases where the 1 stalk was planted every 15 in. with rows 4 in. apart (E. S. R., 9, p. 595).

"When the yields of shelled corn per acre are compared it will be seen that a somewhat different relation holds, the largest amount with the white dent being produced where there were but 2 stalks every 15 in.; but with the smaller variety of Pride of the North dent the largest yield of corn coincided with the largest yield of dry substance where irrigation was practiced, but where the natural rainfall produced the crop the largest amount of shelled corn was associated with the thinnest seeding, and it is a noteworthy fact that this yield is almost as large as where the water was applied, showing that with so thin a stand there was nearly water enough in the season's rainfall for maximum yields."

Analyses of the grain indicate that the thinnest seeded corn was somewhat the richest in nitrogen.

Cost of irrigation in 1897.—With an ordinary farm engine using coal at \$5 per ton, 28.87 acre-in. of water per ton of coal was raised 26 ft. through a 6-in. pipe, at a cost of 17.32 cts. per acre-inch. With a 2½-horsepower gas engine, using gas costing \$1.25 per thousand feet, the cost of raising the water 12.85 ft. was 15.75 cts. per acre-inch. "These results make it appear safe to say that water can be pumped to a height of 26 ft. under conditions similar to ours at a cost for fuel not to exceed 20 cts. per acre-inch."

Water used by crops in Wisconsin.—This is a continuation of previous investigations on this subject (E. S. R., 8, p. 293), both in the plant house and in the field. The investigations have included experiments with corn, oats, clover, and potatoes. The results are summarized in the following table:

Water used by different crops in Wisconsin.

Crop.	Number of trials.	Water required per ton of dry matter.
		<i>Acre-inches.</i>
Corn in the field.....	8	2.433
Corn in plant house.....	44	2.386
Difference.....		.047
Oats in the field.....	8	5.011
Oats in plant house.....	12	4.535
Difference.....		.476
Clover in the field.....	24	5.345
Clover in plant house.....	22	5.005
Difference.....		.340
Potatoes in the field.....	8	4.283
Potatoes in plant house.....	6	2.618
Difference.....		1.665

"It will be seen that, except in the case of the potatoes, the difference between the amount of water used in the field and in the plant house is relatively small. In the case of the potatoes the large difference is due to the fact that in the field trials the plants did not develop perfectly."

The completeness with which the water is utilized by crops in the field and in the plant house is briefly discussed.

Agriculture in Russia, C. COURRIÈRE (*Jour. Agr. Prat.*, 1899, I, No. 1, pp. 22-24).—A note on the conditions of Russian agriculture.

Woburn Experimental Farm: Tabulated results of experiments, J. A. VOELCKER (*Jour. Roy. Agr. Soc. England*, 3, ser., 9 (1898), pt. 4, No. 36, pp. 678-726).—The results of rotation tests and experiments on the continuous growth of wheat and barley for the years 1877 to 1897, inclusive, are given in tables and the plan of the experiments is briefly outlined. An account of some of this work has been noted from a previous volume of this publication (E. S. R., 9, p. 199).

Reports of the department of agriculture and horticulture, F. A. HUNTLEY (*Idaho Sta. Bul.* 15, pp. 147-149).—This report briefly outlines the work performed in the line of agriculture and horticulture by the station in 1897 and presents plans for the work during the season of 1898. The work consists mainly of variety, and culture tests of grain, grasses, and garden crops.

The castor-oil plant (*Jour. Jamaica Agr. Soc.*, 2 (1898), No. 12, pp. 528-530).—Notes on the culture of the plant and the preparation of the seeds for the oil mill.

The culture of coffee in Mexico, H. A. TURNBULL (*Bol. Repub. Mexicano*, 2 (1898), pp. 161-169).—A popular article describing the coffee industry of Mexico.

A few hints on maize growing, H. A. TARDENT (*Queensland Agr. Jour.*, 3 (1898), No. 6, pp. 411-420, pls. 2, figs. 4).—Notes are given on the preparation of the land, the selection of seed, and the planting, harvesting, storing, and marketing of the crop.

Growing and breeding oats, A. KIRSCHÉ (*Deut. Landw. Presse*, 26 (1899), No. 6, pp. 45, 46, figs. 2).—A report on experiments in breeding oats, with measurements and weights of the plants obtained.

The potato, A. W. SUTTON (*Jour. Roy. Agr. Soc. England*, 3, ser., 9 (1898), pt. 4, pp. 581-653, figs. 58).—This illustrated monograph discusses the natural distribution of the potato and its introduction into Europe; deterioration of cultivated varieties; the diseases which attack the plant, and the means to prevent them; the manuring of the crop, its composition and comparative food value, and the practice of modern potato culture. The habitat of other tuber-bearing species of *Solanum* is discussed and varieties of potatoes in different parts of the world are described. The different practices in potato culture in various parts of England, Scotland, and in the Channel Islands are outlined.

Experiments with potatoes, C. FRUWIRTH (*Fühling's Landw. Ztg.*, 47 (1898), No. 24, pp. 921-923).—This article reports the results of variety tests, distance experiments, tests of using whole tubers or different-sized cuttings for seed, and a trial of treating seed tubers for the prevention of scab.

New plants for field culture, A. DUBOIS (*Jour. Agr. Prat.*, 1899, I, No. 3, pp. 90-92, figs. 3).—Notes on a new variety of potatoes, a new hybrid wheat, and canaigre.

Experiments with sugar beets in 1897, H. W. WILEY (*U. S. Dept. Agr., Division of Chemistry Bul.* 52, pp. 165, figs. 2, maps 2).—A reprint from the special report on the beet-sugar industry in the United States, 1897 (see p. 740).

The culture of beets and beet seed, P. DOERSTLING (*Fühling's Landw. Ztg.*, 47 (1898), No. 22, pp. 857, 858).—A popular note.

The velvet bean (*Florida Agr.*, 25 (1898), No. 13, p. 196).—Notes are given on the value of the velvet bean as a soil renovator and forage crop, with directions for its culture.

Florida velvet bean (*Jour. Jamaica Agr. Soc.*, 3 (1899), No. 1, pp. 14-16).—A general discussion of the value of the velvet bean and its botanical relationship.

Varieties of winter cereals, TRIBONDEAU (*Jour. Agr. [Paris]*, 1898, II, No. 1675, pp. 1036-1030).—Brief descriptions are given of a number of different varieties of winter grains. The results of several fertilizer experiments in connection with the tests of these varieties are reported.

Report on experiments carried on at Kloster Hadmersleben in 1897-98 with different sport varieties of grain, F. HEINE (*Deut. Landw. Presse*, 25 (1898), No. 81, p. 868).

Notes on the culture of wheat (*Queensland Agr. Jour.*, 3 (1898), No. 6, pp. 399-410, pls. 3).—Notes on seeding, harvesting, and stacking wheat. Descriptions of a number of varieties of wheat and barley are given.

Natural cross fertilization of oats and "change of seed," T. JAMIESON (*Proc. Agr. Research Assoc. [Scotland]*, 1897, pp. 31-50, fig. 1).—This article is a discussion of the practice of changing seed and a report on experiments in natural cross fertilization of oats. The terms high breeding, cross breeding, mongrels, and natural and artificial crossing are defined. From the results of the experiments the author concludes that oat plants cross freely when grown side by side, that the wind is a sufficiently effective pollen carrier for this purpose, that naturally crossed seeds produce heavier plants than seeds that have not been so crossed, and that crossing may be accomplished on a large scale by mixing the seeds of 2 varieties or differentiated strains and then sowing the resulting seeds the following year.

Cross breeding of wheat (*Queensland Agr. Jour.*, 3 (1898), No. 5, pp. 335-338).—Notes on the objects and methods of cross breeding wheats with regard to the requirements of good milling wheats.

The wheat-growing capacity of the United States, E. ATKINSON (*Pop. Sci. Mo.*, 54 (1898), No. 2, pp. 145-162).

The mineral requirements of grain and the fertilizer applications in spring, L. GRANDEAU (*Jour. Agr. Prat.*, 1899, I, No. 1, pp. 12-14).—A popular article discussing the utilization of plant food by grain at different stages of growth and its relation to fertilizers applied in spring.

Field experiments with fertilizers in 1895, EDLER (*Jour. Landw.*, 46 (1898), No. 4, pp. 349-365).—This article is a review of the results obtained from work begun by the late Dr. Liebscher, of Göttingen. Cooperative fertilizer experiments were conducted with a view to determining the fertilizer requirements of cultivated soils and the results obtained by the different experimenters are here reported. The author states that owing to lack of uniformity in the conditions no conclusions can be drawn.

Experiments with nitrogenous fertilizers on hoed crops, G. DUSSEY (*Chron. Agr. Canton Vaud*, 11 (1898), No. 23, pp. 668-672).—The results of experiments with nitrogenous fertilizers on fodder beets are reported. The yields were profitably increased, the amount of dry matter in the beets remained the same, the proportion of protein was considerably increased, and the sugar content slightly diminished.

Box experiments, J. D. KOBUR (*Meded. Praefstat. Oost Java*, 3, ser., 1898, No. 7, p. 11).—An account of experiments with different fertilizers on sugar cane, including detailed analyses (fertilizing constituents) of the canes and blades and sugar content of the canes.

Residual effects of fertilizing oats and clover, sown together, with Thomas slag and superphosphate (*Deut. Landw. Presse*, 25 (1898), No. 91, p. 957).—The land on which the tests were made received a general application of nitrate of soda. The application of Thomas slag and superphosphate furnished 36.84 lbs. of citrate-soluble and 26.59 lbs. of water-soluble phosphoric acid per morgen (0.63 acre), respectively. The Thomas slag plots gave somewhat better yields of oats than the superphosphate plots, and the following year the Thomas slag plots also produced the largest yields of clover. The differences in the yields of clover were much more marked than the differences in the yields of oats.

Curing cigar tobacco, R. S. NEVILL (*Queensland Agr. Jour.*, 3 (1898), No. 5, pp. 342, 343).—Instructions for curing cigar tobacco and directions for packing the cured product for the market.

HORTICULTURE.

A comparison of the "Station" tomato with three standard varieties, E. S. GOFF (*Wisconsin Sta. Rpt. 1897, pp. 303-306*).—This tomato was produced by crossing the French Upright or Tree Tomato with the Alpha, and has been developed by the author since 1883. Tables are given showing the comparative yield, earliness, and percentage weight of seeds of the Station, Dwarf Champion, Acme, and Nichol Stone varieties. The advantages claimed for the Station tomato are the superior earliness, productiveness, and freedom from decay of the fruit; and the compactness, stockiness, and hardness of the plants.

On the structure of the epidermal layer and the cause of the varying keeping qualities of pomaceous fruits, A. ZSCHÖRKE (*Landw. Jahrb. Schweiz, 11 (1897), pp. 153-196, pls. 2*).—The author states that the keeping qualities of fruit are determined by both mechanical and chemical conditions. Chief among the former are the number of stomata, lenticels, and abrasions in the epidermis by which fungi gain access to the flesh of the fruit. The principal chemical conditions are the presence of acids and tannin which generally hinder or prevent fungus growth. Keeping quality in the more restricted use of the term is, however, dependent mostly on physiological conditions and processes within the fruit. The causes of rotting, dotting, and water core of apples and soft overripeness of the pear are discussed.

The application of artificial root pressure to recently transplanted trees, E. S. GOFF (*Wisconsin Sta. Rpt. 1897, pp. 272-282, figs. 4*).—The author reports experiments in the application of water pressure to the roots of trees as a means of promoting the starting of their buds and thereby preventing failure in transplanting. A small quantity of distilled water was supported at a height equal to or slightly exceeding that of the tree, and connected by a tube with the cut end of one of the roots of the tree. The effect of the water pressure was often very quickly noticed, sometimes within 48 hours. Pressure was applied in the latter part of May, 1896, to a small, purple beech tree which had been planted in April but had shown no indication of opening its buds. Six days later the buds had opened sufficiently to show the leaves plainly. In the Middle of May water pressure was applied to a tree of the City plum which had been planted nearly a month previous. Several leaf buds had opened but had been dried up by hot, dry weather. A week after the pressure was applied many buds which had not opened before began to swell, and in about another week the leaves were pushing out vigorously.

In the spring of 1897, 20 Whitney crab apple trees were planted in rather poor, dry soil. During the 4 days preceding planting, the roots were exposed to the air but protected from the rain and snow. The trees were planted in the latter part of April without special care, and water pressure was applied to a root of each alternate tree. In one week after planting the buds on the trees supplied with water pressure began to open, and in 2 weeks every tree thus treated was starting well. During

the next 2 weeks with dry, clear weather, the treated trees continued, with one exception, to expand their leaves. By this time the buds on one of the untreated trees began to start, but those on the other untreated trees showed no sign of starting. Later the ground was well irrigated and mulched. All the trees ultimately grew except 2, both failures being in the untreated lot. By fall little difference could be seen between the trees of the treated lot and the live ones of the untreated lot, showing that the advantage of the treatment is only in starting growth. The results of these experiments are shown in figures from photographs.

Trees taken up, removed to a building, injected with water, and returned to their places started promptly after the treatment, the results being striking in some cases. In all cases deciduous trees less than 4 years old were used. The amount of water absorbed from the apparatus up to the time of expansion of the leaves was rarely over 10 cc. The apparatus used in the tests consisted of an inverted flask of water supported on a post by the side of the tree and connected by rubber tubing with a root of the tree. Air was admitted to the flask through a short glass tube. A simpler form of apparatus is recommended for ordinary use consisting of an open cup of galvanized iron soldered to the upper end of a piece of small gas pipe, the lower closed end of which is placed in the ground near the tree. Near the end of the pipe a T is inserted as an outlet for the water and a rubber tube connects the T with the root of the tree.

A test was made to ascertain to what extent slight pressure promotes absorption of water by living wood. A small apple scion was immersed in distilled water and another similar one was connected with distilled water under pressure of between $5\frac{1}{2}$ and $5\frac{3}{4}$ ft. and left exposed to the air. In about 18 hours water was forced through and dropped from the scion connected with the water pressure. In 118 hours the immersed scion had increased about 17 per cent in weight and the other nearly 26 per cent.

In regard to the practical value of this treatment of trees the author says:

"Trees of which the bark is shriveled and the buds blackened by undue drying, or of which the roots have been killed by severe freezing in dry soil, can not be saved by this treatment. But trees of which the bark and buds are plump, that are unable to expand their leaves, even when the soil about their roots is moist, may generally be assisted to do so by the apparatus here described. The treatment will probably have especial value for trees that it is desired to plant without severe cutting back of the top."

Orchard cultivation, T. J. BURRILL, and J. C. BLAIR (*Illinois Sta. Bul. 52, pp. 105-127, figs. 13*).—In this bulletin the common cause of failure of orchards in Illinois is attributed to the summer drought and the lack of proper cultivation and care to counteract the ill effects of the dry period. Experiments in orchard cultivation and management begun at the station in 1887 are reported and results are presented in

tables and by means of illustrations. In 1890, 3 rows each of Ben Davis and Grimes Golden apple trees were planted. The plantation was divided into 5 plats, 1 of which was cultivated clean, 1 was cropped with oats, 1 with corn, 1 with clover, and 1 was seeded with blue grass. The treatment of the plats has since been continued as at the outset. Typical trees from each of the plats are illustrated. "The marked inferiority of the trees from the oats and grass plats, particularly the latter, may be seen at a glance; while the superiority of the one from the clean cultivation plat, as regards vigorous and healthy appearance and wealth of foliage, is almost equally apparent." The trees in the plat receiving clean cultivation and the corn plat proved superior to those in the grass plat in character of foliage and size of trunk. Measurements show the trees on the corn plat to be slightly larger than those on the clean cultivated plat, but the authors think it would be an error to conclude that cropping an orchard with corn is beneficial. The root-system of the trees in the clean cultivated plat was compact and deep in the soil, while in the other plats the roots ranged nearer the surface and extended farther. Of the 5 methods tried, the results on the whole indicate that clean cultivation is the best, and that cropping with corn, clover, oats, and grass are less desirable in the order named, and that "under no circumstances should hay or any grain crop be grown on orchard land." The percentage of moisture in the first 27 in. of the soil of the 5 plats was shown by analyses made during October 1897 to be as follows: Clean cultivated 12 per cent, corn 12 per cent, clover 10 per cent, oats 8 per cent, grass 8 per cent. During 1897 the main orchard at the station was cultivated 13 times after the spring plowing, at a cost of \$16 per acre. or 32 cts. per tree. The tools employed were the ordinary plow, roller, and disk, and spring-tooth and smoothing harrows. Remarks are made on the methods of cultivation and on the preparation of the soil for planting orchard trees.

The green gage group of plums, F. A. WAUGH (*Gard. Chron.*, 24 (1898), No. 627, pp. 465, 466).—A history of the group with a discussion of its botanical relationships and position. This study grew out of the author's attempt to trace the 14 varieties of *Prunus domestica* distinguished by Linnaeus (*E. S. R.*, 10, p. 640). The green gage group is believed to be the one that gives the best key to the horticultural evolution of the whole species. A chronological conspectus of the more important references to these plums from 1671 to the present time, and a bibliography of the group in America are presented. Their progressive distribution in Italy, France, and England is traced. It is believed that the group was first introduced into America from England where it was known as Green Gage, and later importations of the same tribe were made from France under the name Reine Claude. At the present time the author finds 2 principal varieties of this type in the market: (1) Green Gage, with dwarfish tree, fruit small and early; and (2) Reine Claude de Bavay, which is a stronger growing tree, with fruit later,

larger, and better. Besides these there are numerous varieties of the same groups named and recognized but having only local importance.

The composition of fresh fruits, A. GIRARD (*Bul. [Min. Agr. France], 17 (1898), No. 7, pp. 1523-1528*).—Detailed analyses are reported of fresh strawberries, raspberries, currants (white and red), cherries, figs, apricots, peaches, plums, grapes, pears, apples, and oranges. In nearly every case several varieties were analyzed. The article has a prefatory note by L. Lindet. Several of the analyses follow:

Table showing analyses of red and white currants and the mandarin orange.

	Average weight of fruit.	Skin.	Seed.	Composition of pulp.							
				Water	Protein.	Saccharose.	Reducing sugar.	Acid ^a	Pectin.	Crude fiber.	Ash.

The protection of orange groves against frost (*Florida Agr., 25 (1898), No. 10, p. 117; Florida Farmer and Fruit Grower, n. s., 10 (1898), No. 10, p. 147; Pacific Rural Press, 55 (1898), No. 11, p. 170*).—This is the report of a committee appointed by the Riverside (California) Horticultural Club to investigate the various methods suggested for the protection of orange groves against frost. The committee, assisted by some 15 or 20 persons interested, made tests of the numerous methods of frost protection and compared protected orchards with neighboring unprotected ones.

It was found that the temperature in the orchards could be materially raised by the use of dry heat. Burning coal in wire baskets proved the most effective method of warming orchards. Oil pots made a hotter fire, and were neither expensive nor difficult to manage, but the deposit of lampblack upon the fruit made the method unfit for general use. With coal, 20 to 50 fires per acre gave good results. In several cases 20 fires per acre raised the temperature 3 to 5°. The expense of keeping up coal fires for a few nights during the coldest weather is so small in comparison with the value of an orange crop that the method is considered feasible. The 50 wire baskets cost about \$5, and the fuel to run them from \$2.50 to \$3 a night.

The possibility of raising the dew point, by means of steam-producing apparatus, sufficiently to prevent injury on dry, cold nights was thought impracticable. It was found that flooding was of considerable value when used in connection with dry heat or smudges. Covering trees with cloth or matting is considered very effective, but the expense is too great.

The use of moist smudges, made by burning damp straw, very considerably lessened the loss of heat by radiation, especially when they were started early. The results obtained by this means are less

definite, however, than those obtained by the use of dry heat. It is considered a valuable means of protection in localities where the temperature falls but little below the danger point, and where there is a considerable area of orchards together.

The temperature in groves protected by wind-breaks was found to be almost invariably from 1 to 2° higher than in exposed orchards in the immediate neighborhood.

The degree of cold endurable by flower buds of the plum and cherry, E. S. GOFF (*Wisconsin Sta. Rpt. 1897, pp. 309-313, dgm. 1*).—Observations at the Wisconsin Station, with notes from the New York State Station, indicate that flower buds of varieties of the native plum endure without harm a greater degree of cold than those of varieties of the European plum (*Prunus domestica*) or Japan plum (*Prunus triflora*). In Wisconsin during the winter of 1895-96 the temperature at the station was not lower than -13° F., and the flower buds of 8 varieties of *Prunus domestica* were uninjured. During the winter of 1896-97 the temperature was lower than -13° F. on 3 days, and was -23° on one night, and all the flower buds on the same varieties were destroyed, excepting a few on "Orel 20." The flower buds of the cherries Dye House, Large Morello, and Late Morello suffered less from the cold than the buds of the European varieties.

Is the ripening season of a pistillate strawberry affected by the blooming period of its pollenizer? E. S. GOFF (*Wisconsin Sta. Rpt. 1897, pp. 283-285*).—The influence of the pollen of Michel Early, Wilson, and Parker Earle upon the ripening season and fruitfulness of the Warfield strawberry was tested. The experiment was conducted during 2 seasons. The different plats covering about one-half acre were grown under conditions as nearly uniform as possible. The yield of fruit from each plat at each of 12 pickings in both seasons is given in tabular form and the results are summarized by the author as follows:

"When the Warfield was pollenized by Michel Early, an early bloomer, 68.8 per cent of the total crop was gathered in the first 6 pickings. When the Warfield was pollenized by Wilson, an early bloomer, 65 per cent of the total crop was gathered in the first 6 pickings. When the Warfield was pollenized by Parker Earle, a late bloomer, 56.3 per cent of the total crop was gathered in the first 6 pickings."

The average yield for the 2 seasons from the rows pollenized by the early blooming strawberries was somewhat larger than that from the rows pollenized by the late blooming strawberry, but the author suggests that this difference might easily result from an imperceptible variation in the soil.

Cold vs. warm water for greenhouse plants, F. CRANFIELD (*Wisconsin Sta. Rpt. 1897, pp. 317-320, figs. 2*).—An experiment was conducted to determine the temperature of water best suited to the growth of certain plants under glass. Cuttings of equal length were taken from the top shoots of a single plant of the Golden Bedder coleus and placed in 4 equal compartments of an ordinary greenhouse flat.

The same was done with the *Verschaffeltii* coleus. The temperature of the water applied to the compartments, numbered 1, 2, 3, and 4, was respectively 35, 50, 65, and 86° F. There was no noticeable difference in root development at the end of 12 days, when the cuttings in each compartment were potted and each lot was watered with water of the same temperature as before. A table shows the growth at 60, 70, and 90 days after the cuttings were taken. At 90 days the plants in lot 1 were about 18 per cent. smaller than those in the other 3 lots, which were practically equal, indicating that "the coleus may be watered with water of a temperature from 50 to 80° F., and that there is little choice between these temperatures." Temperature readings taken before watering and at intervals of 1 hour after showed that the temperature of the soil in lot 1 was perceptibly lowered by the watering, and at the end of 3 hours it had not regained its original temperature. In lots 2, 3, and 4 the temperature of the soil was little changed by the watering.

A similar experiment was made with 48 Lorillard tomato plants of uniform size at the beginning of the experiment. These proved to be more susceptible to water of different temperatures than the coleus. Two months after transplanting the plants given water at 35, 50, 65, and 86° F. measured in height 318, 363, 368, and 358 mm., respectively, the best results being obtained apparently with water at 65° F. The experiments are to be repeated on plants growing under outdoor conditions.

Notes on watering. F. CRANFIELD (*Amer. Florist*, 14 (1898), No. 539, p. 256).—Much of the data in this article is given in the preceding article. After 2 years' work the author believes the following statements can be made: "(1) Water at 35° F. does not injure coleus, begonias, nor geraniums; (2) similar plants treated with water at 50° F. grow equally as well as those watered with water at 65 and 86° F." Warm water appeared to produce an elongated or "drawn" growth, while cold water made the plants short jointed and stocky but well colored and healthy. Though the plants given warm water grew taller they weighed slightly less than those given water at a temperature of 50° F.

Bush fruits. F. W. CARD (*The Macmillan Co., New York, 1898, pp. XII + 537, figs. 113*).—This book is one of the Rural Science Series and the first of a proposed series of monographs on the various types of American fruits. The purpose of the work is to present all important phases, both practical and technical, of bush fruit culture and domestication. Bush fruit management in general, comprising location, culture, and marketing, are discussed. Bush fruits are classified as brambles, groselles, and miscellaneous types. The brambles comprise the red raspberry, black raspberry, blackberry, dewberry, oriental raspberry, mayberry, strawberry-raspberry, wineberry, and Chinese raspberry. Certain ornamental species of brambles are also included. The groselles comprise currants and gooseberries. Miscellaneous types occasionally met with, though of no commercial importance in cultivation, are the Buffalo berry, goumi, huckleberry, juneberry, tree cranberry, barberry, and sand cherry. The management of each type of commercial importance is comprehensively

discussed, and an attempt is made to estimate the average yield and profits per acre under favorable conditions of culture.

Notes are given upon the history and future of each type of importance, including as complete a list as possible of varieties, with recommended sorts. The insects and diseases affecting brambles and groselles respectively are enumerated, and those of economic importance are briefly discussed. A systematic study of *Ribes* and *Rubus* is made, in which all species, native or cultivated, in America, north of Mexico, are classified and described. The editor has added an appendix of American books treating in part of bush fruits. The usefulness of the book to both grower and student is much enhanced by the treatment of practical and technical subjects in separate chapters.

Measures for the promotion of horticulture and forestry in Sweden, Denmark, Germany, and Austria, J. SMITH (*Tidsskr. Norske Landbr.*, 5 (1898), No. 5, pp. 215-235).

The principles of fruit-tree culture, E. LUCAS and F. MEDICUS (*Stuttgart: I. B. Metzler, 1898, pp. 482 + XVI, ill.*).—A text-book.

Observations of the relative moisture content of fruit trees in winter and in summer, C. S. CRANDALL (*Proc. Amer. Assoc. Adv. Sci.*, 47 (1898), pp. 405-407).—A report is given upon a series of investigations which the author conducted with samples of trunks and branches of apple trees taken January 15 and 16 and August 3. The specimens were thoroughly air dried, carefully weighed before and after the drying, and the percentage of loss in each case is given in a table. From the trial made it seems reasonable to conclude that there was hardly any appreciable difference between the winter and summer moisture contained in apple trees, at least when grown under Colorado conditions.

Some conditions which influence the setting of fruit, S. A. BEACH (*East. New York Hort.*, 2 (1898), No. 2, pp. 6, 7).—This is a paper read before the Eastern New York Horticultural Society. The author enumerates the following factors which influence in a most marked degree the development of fruit buds and thereby the production of fruit, and which are largely under the control of the fruit grower: "The kind and quantity of fertilizers which are applied to the soil, the supply of moisture in the soil, the condition of the foliage, and the directing of the supply of plant food to different parts of the plant by judicious pruning. Those things which are beyond the fruit grower's control, and which combine to vary the results, are temperature, light, and atmospheric moisture."

Manurial requirements of orchard and fruit trees, J. J. WILLIS (*Gard. Chron.*, 3. ser., 25 (1899), No. 630, p. 36).—A discussion of principles.

History of the Gano apple, H. E. VAN DEMAN (*Amer. Gard.*, 20 (1899), No. 215, p. 81).

A preliminary study of the prickly pears naturalized in New South Wales, J. H. MAIDEN (*Dept. Agr. New South Wales, Misc. Pub.* 253, pp. 30, pls. 6).—Extracts from the law providing for the eradication of the prickly pear, with notes upon its administration. Notes on the prickly pear in other countries and a brief bibliography of the prickly pear as a fodder plant are given. The species naturalized in New South Wales are described and the synonymy discussed.

A new fruit (*Tidsskr. Norske Landbr.*, 5 (1898), No. 11, p. 566).—A French botanist, Andrée, has found a new fruit tree in his travels in the Argentine Republic (La Plata). The tree, *Feijoa Sellowiana*, is 3 to 5 meters high. The fruit is an elongated egg-shaped berry, 4 to 6 cm. long and 3 to 5 cm. broad; it retains its green color when ripe. The meat of the fruit is firm, white, very juicy, and sweet, and tastes much like pineapple. The tree is now planted in the south of France, where it thrives excellently. If it will grow in other parts of Europe, Andrée is of the opinion that it will prove a valuable southern fruit for Europe.

Small fruits, E. S. GOFF (*Wisconsin Sta. Rpt.* 1897, pp. 313-316).—Notes and variety tests on European cherries, strawberries, gooseberries, golden mayberry, strawberry-raspberry, and currants.

Cranberry growing in Nova Scotia, J. CRAIG (*Amer. Gard.*, 20 (1899), No. 214, p. 63, figs. 2).

The strawberry-raspberry, W. E. BRITTON (*Amer. Gard.*, 20 (1899), No. 215, p. 63, figs. 2).—Descriptive and cultural notes.

Nutrition and protection of the vine by injection, L. MANGIN (*Jour. Agr. Prat.*, 1898, II, No. 52, pp. 918-920).—Statement and unfavorable criticism of Berget's theory that the vine may in practice be protected from the attacks of fungi by injection of copper salts into the stem and advantageously nourished by injection of a solution of phosphate of ammonia.

The productiveness of grafts on *Vitis rupestris* and *V. riparia*, J. M. GUILLOX (*Jour. Agr. Prat.*, 1898, II, No. 51, pp. 899, 900).—Abstract of a bulletin of the viticultural station of Cognac. The comparative productiveness of grafts on these stocks is studied. The must of *rupestris* was found to contain 148 gr. sugar per liter, *riparia* 191 gr.

Packing and shipping fruits, C. C. BELL (*Gardening*, 7 (1899), No. 153, pp. 138-140).—A paper read at the last annual meeting of the Illinois Horticultural Society.

Preservation of fruits in lime (*Belg. Hort. et Agr.*, 10 (1898), No. 24, p. 378).—In experiments in France grapes packed in lime for 7½ months were found still very fresh. Winter pears and quinces which otherwise could be kept only 2 or 3 months were preserved until fully ripe. It is stated that lime does not retard decay when produced by physiological causes. It protects the fruit only from external causes of decay, such as dampness, vermin, insects, and microbes. With the use of lime it is not necessary to make any special provision for storage.

Preserving in tins, or the art of canning, A. M. HOWELL (*Agr. Gaz. New South Wales*, 9 (1898), No. 10, pp. 1181-1190, figs. 6).—Methods of canning on a small scale. Among the subjects treated are canning in tins with solder, the home cannery, the wax-sealing method, standard methods, exhausting the cans of air, testing cans for leaks, the sterilizing process, and general formulas for canning.

Pulping fruit (*California Fruit Grower*, 24 (1899), No. 4, p. 4).—Notes upon the process in Australia and the utilization of the product.

The use and construction of greenhouses for horticulturists, L. R. TAFT (*Florists' Exchange*, 11 (1899), No. 4, pp. 73, 74; *Gardening*, 7 (1899), No. 154, pp. 153-155).—Abstract from a paper read before the Missouri State Horticultural Society.

The water garden, W. THICKER (*New York: A. T. De La Mare Printing and Publishing Co., Ltd.*, 1897, pp. 120, pls. 27, figs. 20, dqms. 5).—The work discusses the construction of ponds, adapting natural streams, planting, hybridizing, seed saving, propagation, building an aquatic house, wintering, correct designing and planting of banks and margins, together with cultural directions for all ornamental aquatics. Descriptive notes with cultural memoranda are given for water lilies, miscellaneous aquatic plants, orchids, ferns, and hardy perennials, hardy shrubs, and trees suitable for wet or moist situations. The illustrations represent various cultivated aquatics and treatment of water scenes in landscape gardening. Artificial ponds and an aquatic house are figured. The plates are numerous and artistically executed.

Further notes on watering, F. CRANFIELD (*Gardening*, 7 (1899), No. 154, pp. 152, 153).—A continuation of experiments reported on page 756, with similar conclusions.

Cultural directions for begonias, C. W. RANKIN, A. E. LEY, and P. B. KENNEDY (*Amer. Gard.*, 20 (1899), No. 213, pp. 45, 46, pls. 4).—Papers submitted in competition for a prize.

Propagating ferns (*Garden*, 55 (1899), No. 1418, p. 33).

Phacelias (*Garden*, 55 (1899), No. 1418, pp. 36, 37, pl. 1).—Botanical and cultural notes.

Grafted roses, R. CRAIG (*Amer. Gard.*, 20 (1899), No. 214, pp. 61, 62).

The principles of rose pruning (*Success with Flowers*, 9 (1899), No. 5, pp. 97-99, figs. 5).

SEEDS—WEEDS.

The influence of varying amounts of water on the germination of beet seed, E. S. GOFF (*Wisconsin Sta. Rpt. 1897, pp. 299-302, figs. 2*).—The author states that in testing seed in a Geneva tester he frequently noted the influence of varying amounts of water in the cloth. This is more apparent with beet seed than with other species which have been tested. If the corky covering becomes saturated with water, the oxygen may be so far shut out as to prevent germination. In order to test the influence of varying amounts of water on germination a series of experiments was conducted with 22 lots of beet seed from various sources. In one apparatus the ends of the cloth of the Geneva tester were constantly immersed in the water of the pan, the level of which was slightly below the bottom of the pockets. In the other the cloth was wrung out as nearly dry as possible without removing the wires and placed in the empty pan and no further water was added. In this apparatus provision was made against undue evaporation. One hundred seed balls of the sugar-beet seed were placed in each pocket and the 2 testers were placed in the horticultural laboratory, in which the temperature varied during the test from 70 to 90° F. The average germination from the 2 testers showed a difference of 50 plantlets for each 100 seed balls in favor of the drier cloth. It would appear from these results that the germination of beet seed in the open ground is liable to be prevented by excessive water in the soil.

Resistance of seed to immersion in water, H. COUPIN (*Compt. Rend. Acad. Sci. Paris, 126 (1898), No. 19, pp. 1365-1368*).—On account of the importance of water as a factor in seed dissemination, the author has made a study of the effect on the vitality of seed of their prolonged immersion in water. Some of the injurious effects are pointed out, notably the osmotic pressure of liquids in the cells, the loss of soluble material in seed, the presence of bacteria which dissolve cellulose and produce butyric fermentation, the lack of oxygen, and finally the attack of various low organisms. In one set of trials the water was changed every 24 hours, while in the other it remained unchanged from the beginning of the experiment. The following table shows the length of time seeds were immersed in water before their vitality was destroyed.

Number of days within which seed vitality was destroyed by soaking.

Kind of seed.	Water changed.	Water not changed.	Kind of seed.	Water changed.	Water not changed.
	<i>Days.</i>	<i>Days.</i>		<i>Days.</i>	<i>Days.</i>
Beets.....	148	30	White mustard	7	5
Mullein.....	115	49	Mallow.....	6	10
Leeks.....	90	45	Sunflower.....	110
Asparagus.....	75	145	Stock.....	20
Borage.....	57	28	Castor bean.....	68
Anise.....	57	21	Harry vetch.....	45
Sweet fennel.....	39	30	Crimson clover.....	32
Poppy.....	27	25	Cytisus.....	30
Flax.....	13	12	Hemp.....	12
Wheat.....	10	17	Maize.....	10
Oats.....	9	11	Buckwheat.....	3
Millet.....	9	6			

A second series of experiments was conducted to test the effect on germination of immersion in running and still water. Comparable lots of different seeds were immersed in running and still water for 24 and 48 hours with the following results:

Effect of soaking on percentage of germination of seed.

Kind of seed.	In running water.		In still water.	
	24 hours.	48 hours.	24 hours.	48 hours.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Buckwheat	81	70	55	52
Wheat	99.6	100	64	97
Maize	85	89	84	80
Peas	98	97	94	85

In addition to the facts shown in this table, it is found that still water not only destroys the germinative ability of some seeds, but also retards it in others. In the case of buckwheat placed in running water, most of the seeds germinated within 24 hours after being placed in the germinating chamber, while those soaked in still water did not germinate until after the second day.

The flaxseed in its botanical, chemical, and agricultural relations (*Der Lein-same in botanischer, chemischer und landwirtschaftlicher Beziehung: noted in Deut. Landw. Presse, 25 (1898), No. 59, p. 660*).

On the ripening of seed, W. JOHANSEN (*Abs. in Norsk Landmandsblad, 17 (1898), No. 35, pp. 373-375; 36, pp. 384-386; 37, pp. 399-402*).

Combating juncus in meadows and pastures (*Deut. Landw. Presse, 25 (1898), No. 81, p. 869*).—Recommends addition of lime, kainit, and other fertilizers.

Combating mustards with iron sulphate (*Deut. Landw. Presse, 25 (1898), No. 48, p. 523; 60, p. 667*).

The Russian thistle in Washington, C. V. PIPER (*Washington Sta. Bul. 34, pp. 18, pls. 2*).—The author notes the occurrence of the Russian thistle (*Salsola kali tragus*) in a number of places throughout the State, and a description of the plant is given with suggestions for its destruction. Numerous weeds which are sometimes mistaken for the Russian thistle are briefly described, and an appeal made to farmers to prevent the spread of this pest.

Twelve of Idaho's worst weeds, L. F. HENDERSON (*Idaho Sta. Bul. 14, pp. 91-136, pls. 13, figs. 5*).—Descriptive notes are given of 12 of the worst weeds of Idaho, together with the methods by which they are distributed and suggestions for their eradication. The following is a list of the weeds: Wild oats, prickly lettuce or compass weed, Russian thistle, tumbling mustard, cow herb, Canada thistle, dodder, false flax, sunflower, squirrel-tail grass, common tumbleweed, and horehound.

Report of the botanist and entomologist, C. V. PIPER (*Washington Sta. Rpt. 1896, pp. 29-39*).—The author briefly reviews the laboratory work of the year, gives notes on the occurrence of the Russian thistle, and states that a bulletin is in course of preparation in which attention will be called to the most serious weed pests of the State. Need of a revision of the State weed law is pointed out, and notes are given on the herbarium and field botanical work of the season. The entomological work of the season is briefly described, and reference made to the more common injurious insects (*E. S. R., 8, p. 321*).

DISEASES OF PLANTS.

Potato diseases, E. ROZE (*Gard. Chron.*, 3. ser., 21 (1898), No. 608, p. 131.)—The conclusions of the author as to the cause of various potato diseases are given. He states that the dry rot is produced by *Pseudocommis vitis*, in which case the tubers are free from any odor, but show depressed dark spots in the parenchyma with a brownish band surrounding. These tubers can be kept until spring, when they develop shoots which bear brownish or blackish tips. Dry rot may also be produced by a species of *Micrococcus*. In the case of this form of attack the tubers are said to be free from odor, moderately firm, more or less soft in spots, but showing in certain places a loose epidermis which yields to the pressure of the finger. Under this epidermis the parenchyma exhibits white, gray, or brownish blotches. Sometimes there are depressions which exhibit the sclerotia of *Rhizoctonium* or later an abundant development of *Fusisporium* and *Spicaria*.

The wet rot is produced by a species of *Micrococcus* closely allied to *Bacillus subtilis*. The tubers are partly or wholly soft and exhale a very disagreeable odor. Under the epidermis there is a disintegration of parenchyma with an elaboration of butyric acid. Destruction is slow and progressive and contact with healthy varieties should be avoided. Wet rot is also said to be produced by *Phytophthora infestans*, in which case there is a partial or complete softening of the tissue, the epidermis is shrunken, the parenchyma which is weakened is depressed, pasty, but not deliquescent. The author states that of the different forms of potato rot at least 50 per cent of the tubers are attacked by *Micrococcus* sp. and 25 per cent by the *Pseudocommis*, while a still smaller amount is due to *Phytophthora*.

The remedies recommended are alternation of crops, planting of healthy tubers, destruction at harvest of all diseased potatoes, and treatment of the plants with copper fungicides.

Diseased potatoes, G. ABBEY (*Jour. Hort.*, 50 (1898), No. 2620, pp. 463, 464, fig. 1).—Specimens of some badly infested tubers were submitted to the author for examination, and he reports finding in one of them several wireworms and quite a number of small forms closely related to the springtails. In another specimen several protuberances of various kinds were noted, some just beginning, while others were in a more advanced stage of development. No trace of animal life was discovered in the cracks of the excrescences, which were black and moist, the warts being brown and scabbed. A closer examination of these tubers showed the presence of the scab fungus *Oöspora scabies*, but the main trouble, the author states, could not be attributed to this cause. A slimy fungus closely related to the *Plasmodiophora* was present in abundance. It is stated that it may be *Pseudocommis vitis*, although the resemblance is not sufficiently clear. Besides the various parasites already mentioned there were found present *Bacillus amylobacter*, the mycelium of *Fusarium solani*, a root worm (*Enchytraeus*

minutus), an eel worm (*Tylenchus obtusus*), and the mite *Rhizoglyphus echinopus*.

For the prevention of all these attacks on the potato the author recommends treating the tubers before planting with a solution of corrosive sublimate and planting in soil that has been heavily limed. The application of kainit is also recommended, applications of 10 tons of lime and 10 cwt. of kainit being applied in the fall, the lime to be first plowed under and then the kainit applied as a top-dressing.

The effect of various copper preparations on the potato, R. THIELE (*Ztschr. Pflanzenkrank.*, 8 (1898), No. 2, pp. 70-80).—The author reports the effect of applications of fostite, a copper sucrate solution, a copper, sulphur and lime powder, and copper calcite. Fifty varieties of potatoes were planted in rows, but so arranged in different plats that treated and checked lots were comparable. Some of the results of the applications are tabulated, showing that the different fungicides affected different varieties differently. The potato blight was greatly restricted by the use of all the fungicides except the copper, sulphur and lime powder. The plat where this was applied showed the greatest amount of disease of any of the treated plats and exceeded some of the control plats in this respect.

The influence of the treatment on the yield of different varieties is shown. The gains and losses were about equal. It was apparent, however, that there were a greater number of small tubers on the plants in the sprayed plats than in the others, and the author believes that this was due to the fact that the copper preparations prolonged the growing period of the plants and at the same time checked to some extent the growth of the tubers. He states, however, that if the period of growth could be prolonged sufficiently to mature the small tubers that in all probability the yield would be considerably increased by the application of the fungicide.

A new copper fungicide for combating black rot, J. PERRAUD (*Jour. Agr. Prat.*, 62 (1898), No. 50, pp. 819, 850).—The author describes a form of fungicide which he claims is very efficient in preventing attacks of black rot. The method of preparation is fully given as well as the formula, which consists of water 100 liters, copper sulphate 2 kg., and resin 0.5 kg. Carbonate of soda sufficient to render the solution slightly alkaline is added. Another formula given contains only half of the above amount of copper. This fungicide has been tested and compared with ordinary Bordeaux mixture to which soap was added, and the total amount of copper adhering to the grapes was somewhat higher than in the case of the other fungicide. The tenacity with which it is held upon the fruit and foliage is said to be the most important factor in its favor.

A trial of "Ceres pulver" for the prevention of smut in oats, E. S. GOFF (*Wisconsin Sta. Rpt.* 1897, pp. 307-309).—A comparison was made of Ceres pulver and hot-water treatment as a means of preventing smut in oats. The grain used for seed was from a crop that had

been nearly destroyed by smut the preceding year. Untreated seed produced 10.2 per cent of smutted heads, seed treated with Ceres pulver, 2.7 per cent, and seed treated with hot water, 0.00075 per cent. The author is inclined to believe the amount of water recommended for dissolving the Ceres pulver (3.2 oz. in 10 qt.) is insufficient to saturate the hulls of the oats, and that the use of a little more water might have made the treatment more effective.

Diseases of plants, A. P. ANDERSON (*South Carolina Sta. Bul.* 36, pp. 17, figs. 14).—A brief popular description is given of the different classes of plant diseases due to fungi, bacteria, or other causes.

Disease in vegetable life, W. T. SEDGWICK (*Florists' Exchange*, 11 (1899), No. 3, p. 56).—Abstract of a lecture discussing the lines along which prevention of disease and promotion of health must work. These are stated to be improvement of the mechanism and control and amelioration of the environment, the latter eventually attended by improvement of the organism itself considered as a physical mechanism.

Report of the department of botany, L. H. HENDERSON (*Idaho Sta. Bul.* 15, pp. 151-162).—The author briefly reviews the work of the year and gives notes on the occurrence of and approved remedies for a number of orchard and garden diseases which have appeared in Idaho.

The leaf-spot disease of apple (*Phyllosticta pirina*), and several unrelated forms occurring therewith, W. B. ALWOOD (*Proc. Amer. Assoc. Adv. Sci.*, 47 (1898), p. 413).—The author gives notes on the common occurrence and life cycle of this fungus and mentions the occurrence therewith of 3 apparently unrelated forms, viz., *Sphaeropsis malorum*, *Hendersonia mali*, and an undetermined species.

The apple mildew in the Tyrol, P. MAGNUS (*Ber. Deut. Bot. Gesell.*, 16 (1898), No. 2, pp. 331-334, pl. 1).—Notes the occurrence of *Sphaerotheca mali* on the apple in the Tyrol. It had associated with it *Podosphora* sp.

Monilia fructigena and the Monilia disease of fruit trees, C. WEHMER (*Ber. Deut. Bot. Gesell.*, 16 (1898), No. 2, pp. 298-307, pl. 1).—A sketch is given of the distribution, history, characters of the fungus, nature of its attack, and means for combating the Monilia disease of apple, pear, cherry, etc.

Report on the investigation of the disease of the roots of the mulberry tree on the Caucasus, A. YACHEVSKI (*Selsk. Khoz. i Lyesov.*, 190 (1898), No. 9, pp. 653-660).—According to the author, *Dematophora necatrix* is the cause of the disease of the mulberry tree in the Caucasus.

On the appearance of, and methods for combating, grape injuries in Germany in 1896, MORITZ (*Abs. in Centbl. Bakt. u. Par.*, 2. Abt., 4 (1898), No. 22 pp. 842, 843).—The first part of this work discusses the effect of atmospheric conditions, such as late frosts and hailstorms, and suggests how to overcome their injury.

In the second part of the treatise the author mentions the principal troublesome insects of the grape. Those especially described are *Couchylis ambiguella*, *Rhynchites bebbulei*, *Otiorynchus ligustici*, *Eumolopus vitis*, the cankerworm, *Melolontha vulgaris*, *Phytoptus vitis*, and *Tetranychus telarius*. Among the diseases described and for which remedies are suggested the following fungi are noted: *Peronospora viticola*, *Oidium tuckeri*, *Sphaeloma ampelinum*, *Dematophora necatrix*, *Botrytis cinerea*, and several other diseases of unknown origin.

Investigations on the life history of rust fungi, E. FISCHER (*Entwickelungsgeschichtliche Untersuchungen über Rostpilze*. Bern: K. J. Wyss, 1898, pp. X + 121, pls. 2, figs. 16).—This is a preliminary contribution to a monograph of the Swiss Uredineæ and was published by *Sweiz. Naturforsch. Gesellschaft*.

Descriptions of American Uredineæ, II, J. C. ARTHUR and E. W. D. HOLWAY (*Bul. Lab. Nat. Hist. Univ. Iowa*, 4 (1898), No. 4, pp. 377-402, pls. 11).—Descriptions and notes are given of a number of species of Uredineæ that have been distributed by the authors.

Cereal blights and the liming and sulphuring of the seed grain, E. PIRET (*Agronome, 1898, No. 40*).

The gum flow of the seroh disease of sugar cane, A. WIELER (*Beitr. Wiss. Bot., 2 (1898), pp. 29-140*).

The parasitic diseases of sugar beets (*Agr. Rationelle, 1898, No. 20*).

The biology of some parasitic fungi, M. NORDHAUSEN (*Jahrb. Wiss. Bot. [Pringsheim], 33 (1898), No. 1, pp. 1-46*).—This paper treats of the conditions and manner of infection by *Botrytis cinerea*, conditions of the host plant for successful infection, the occurrence of *B. cinerea* and related fungi in nature, and studies of *Penicillium* and *Mucor* as representatives of saprophytic life.

On the presence of a fungus in *Lolium temulentum*, P. GUÉRIN (*Jour. Bot. France, 12 (1898), No. 15-16, pp. 230-238, figs. 5*).—The author reports finding in the grain of this plant a fungus of a somewhat similar nature to the ergot of rye, and thinks the poisonous properties of the plant may be due to this cause.

Notes on the occurrence of a fungus in *Lolium temulentum*, P. GUÉRIN (*Jour. Bot. France, 12 (1898), No. 23-24, pp. 384, 385*).—Attention is called to the publication by the author in August, 1898, mentioning the presence of a fungus in the grains of the darnel, the name *Endoconidium temulentum* having been given it. This paper seems to have been overlooked by Hanansek and Nestler.¹ The conclusions of the different authors agree in the main, except Guérin finds this fungus on other species than *L. temulentum*, such as on *L. perenne* and *L. linicola*, and its wholly saprophytic nature is questioned.

A comparative study of some anthracoses, B. M. STONEMAN (*Bot. Gaz., 26 (1898), No. 2, pp. 69-120, pls. 12*).

The stem-rot disease of carnations, W. E. BRITTON (*Gardening, 7 (1899), No. 153, p. 138*).—Notes on unsuccessful attempts to check the disease. Destruction of all diseased plants, propagation only from healthy ones, and the use of fresh soil are believed to be the most nearly successful methods of control yet known. Antirrhinums and asters have been affected in a similar manner. That the same fungus attacks these 3 plants is believed to be probable.

A disease of the loquat, G. QUINN (*Jour. Agr. and Ind., S. Australia, 2 (1898), No. 5, pp. 400, 401, fig. 1*).—The occurrence of a destructive disease of loquats, due to *Fusicladium eriobotrya*, is mentioned. The application of Bordeaux mixture has been tried and is recommended for its prevention. All diseased fruits and leaves should be collected and burned.

Rose mildew, G. SCALIA (*Bol. Ent. Agr. e Patol. Veg., 5 (1898), pp. 17-21; abs. in Ztschr. Pflanzkrank., 8 (1898), No. 5, p. 304*).—The author notes an unusual outbreak of this fungus, and states that the atmospheric conditions had been exceptionally favorable for the development and spread of the disease. Sulphur dusted on the plants is recommended as treatment. *Spharotheca pannosa* is also noted as abundant on peach trees.

The clematis disease, J. JENSEN (*Amer. Florist, 14 (1899), No. 555, p. 740*).—Notes are given of the disease, and quotations from various investigators seem to indicate that the trouble is a physiological one. Sorauer is quoted as saying it is due to too much nourishment, water, and heat. The Florida and lanuginosa types seem most subject to the dying off that characterizes this particular disease.

On the presence of *Septoria curvata* on *Robinia*, A. MORI (*Staz. Sper. Agr. Ital., 31 (1898), No. 5, p. 499*).—Notes the attack of this fungus on *Robinia pseudacacia*. The circular brown spots, with their numerous perithecia, are said to be quite abundant on the leaves and have proved very destructive to the trees.

The cause of chlorosis in green leaves, C. MOHR (*Gartenwelt, 2 (1898), No. 48, p. 569; abs. in Bot. Centbl., 76 (1898), No. 8, p. 232*).—The author does not consider chlorosis a disease, and for its prevention recommends the use as a fertilizer of a

¹ Ber. Deut. Bot. Gesell., 16 (1898), No. 8.

strong solution of iron sulphate and lime, in order that the plant should receive sufficient iron.

Eel worms in grape roots, G. ABBEY (*Jour. Hort.*, 51 (1899), No. 2623, pp. 14, 15, figs. 2).—Notes the presence of *Heterodera radicicola* on grape roots. The life history of the nematode and means for its destruction are given. The application to the roots of a solution of 3 oz. of Little's soluble phenyl in 3 gal. of water is recommended. Digging about the roots and applying nitrate of soda and sulphate of ammonia is also recommended.

ENTOMOLOGY.

On the poison of honeybees, J. LANGER (*Arch. Exper. Pathol. u. Pharmacol.*, 38 (1897), pp. 381-396; *abs. in Jahresber. Thier. Chem.*, 27 (1897), pp. 520, 521).—The poison drop, freshly excreted, weighs from 0.0002 to 0.0004 gm. It has a specific gravity of 1.0013, is clear as water, and has a marked acid reaction, bitter taste, and a pleasant aromatic odor. The poison was obtained by collecting the drops or by extracting the entire poison apparatus with alcohol. This caused coagulation, and the poison was taken up by the alcohol. When the alcohol was supersaturated with ammonia and evaporated a yellowish material was obtained. Solutions of this gave reactions of formic acid. The author's investigations, however, showed that formic acid does not possess the poisonous properties of the bee poison. The solution of the poison contains an albuminoid, hydrochloric and phosphoric acids, sodium, and calcium. The albumin does not produce the poisoning, since a solution of the poison freed from it produced poisoning symptoms, as observed on the conjunctiva of a rabbit's eye. Evaporating the poison and heating at 100° does not diminish its properties, nor does keeping it for some time in sealed capillary tubes. On the other hand, when kept in open glass tubes the poisonous properties are lost in about 4 weeks. The poison spoils on standing and loses its toxic properties. The poisonous substance is held in suspension by acid, and can be precipitated by alkali. This shows that the active principle secreted by members of the aculeata group of Hymenoptera is a base.

Report of the department of entomology, J. M. ALDRICH (*Idaho Sta. Bul.* 15, pp. 167-176, fig. 1, pl. 1).—This bulletin gives a brief account of the work of the year and the result of several investigations.

An investigation of the grasshoppers (*Camnula pellucida*) in a few localities in the State is reported. A method which was found very useful in destroying young grasshoppers was to drive them together by partly flooding the ground by irrigation ditches, and to burn them during the cool part of the day through the aid of straw. Where this treatment was impracticable hopperdozers were employed. The young grasshoppers did not jump into the hopperdozer when it was drawn along, but did so when it was left standing and they were driven toward it.

A few experiments were made to determine whether kerosene could be successfully and economically used to rid certain localities of the mosquito plague and to determine how large a pond could be successfully treated. The test did not result satisfactorily.

"The conclusion from this experiment is that kerosene to be effective against mosquito larvæ must cover the surface to a perceptible depth; a mere film will not answer. As the usual market price of the oil in small quantities throughout Idaho is 30 to 35 cts. a gallon, the cost will be prohibitive except in thickly settled communities and on small bodies of water, where the remedy will doubtless be of marked usefulness."

Some differences between the Putnam scale and the San José scale are pointed out. The characteristics, habits, and injuries of the box-elder bug are considered.

Some insects of the year 1897, W. B. BARROWS and R. H. PETTIT (*Michigan Sta. Bul.* 160, pp. 339-436, figs. 29).—Notes are given of 28 species of insects which were more or less troublesome during the season indicated. These were not necessarily the ones that caused the most damage, but as it is considered impracticable to publish in a single bulletin a treatise which shall cover all insect enemies, it is thought the selection made will prove to be the most serviceable. The insects treated are the following: Grasshoppers (*Melanoplus femur-rubrum* and *M. atlantis*), pear psylla (*Psylla pyricola*), aphids of plum, cherry, and apple (*Aphis prunicola*, *Myzus cerasi*, and *A. mali*), black peach aphid (*A. persica-niger*), woolly aphid of apple (*Schizoneura lanigera*), San José scale (*Aspidiotus perniciosus*), eccentric scale (*A. ancyllus*), oyster-shell bark louse (*Mytilaspis pomorum*), white scale of the pine (*Chionaspis pinifoliæ*), scurvy scale of the pear and apple (*C. furfurus*), plum scale (*Lecanium cerasiferæ*), currant scale (*L. ribesii*), cankerworms (*Anisopteryx pometaria* and *Paleacrita vernata*), apple-leaf tier (*Teras minuta cinderella*), bud moth (*Tmetocera ocellana*), army worm (*Leucania unipuncta*), erratic army worm (*Noctua fennica*), zebra caterpillar (*Mamestra pieta*), cat and dog flea (*Pulex serraticeps*), grape-cane borer (*Amphicerus bicaudatus*), cherry-leaf beetle (*Galerucella cavicollis*), asparagus beetle (*Crioceris asparagi*), pear slug (*Eriocampa cerasi*), and white-pine saw-fly (*Lophyrus lecontei*).

On the biology and taxonomy of some species of mining Diptera, W. C. BRASHUIKOV (*Nachricht Moskauer Landw. Instituts*, 3 (1897), pp. 22, pls. 1, and figs.; *abs. in Zool. Centbl.*, 5 (1898), No. 7, pp. 234-236).—Observations were made on the 3 genera of Muscidae—Phytomyza, Agromyza, and Anthomyia. The larvæ of *Phytomyza geniculata* mine the leaves of different Compositæ of *Pisum sativum*, *Cucumeris sativa*, several Cruciferae, etc., and are also polyphagous—a habit not found in other mining Diptera. The eggs are laid on the under surface of the leaves, the larvæ eat through the epidermis of the leaf, and make irregular passages in its interior. In a single leaf 1 or 2 larvæ may be found. Pupation always takes place on the under leaf surfaces, where the larva sticks its head somewhat out of the leaf. The larva

of *P. atra* always mines along the leaf rib. Larva of *P. flavoscutellata* does not pupate in the leaf but hides in the earth; that of *P. bipunctata* mines the upper surface of the leaf and pupates in the earth. The larva of *Agromyza pulicaria* always ends its mined passages with 1 to $1\frac{1}{2}$ spiral turns. Near the time of pupation the larva assumes a lively green color, closely resembling the leaf. The larva of *A. strigata* pupates in the leaf. In *Anthomyia nigratarsis* several larvæ generally mine in the same passage. Sometimes several groups are met with in a single leaf and the latter in such cases is completely hollowed out. This species especially is to be considered as injurious in contrast to the true miners of the last 2 genera.

The author believes that the genera *Phytomyza* and *Agromyza* may have been derived from a form related to *Anthomyia*. To this form *Agromyza* stands nearest, followed by the subgenus *Ophiomyia*.

A new squash bug, F. H. CHITTENDEN (*Canad. Ent.*, 30 (1898), No. 9, pp. 239, 240).—While investigating the insects affecting cucurbits the author discovered that in addition to the common squash bug a second species is present in certain parts of this country. This insect (*Anasa armigera*) has been observed in a number of places around Washington, D. C., and it appears to have very much the habits of the more common squash bug, *A. tristis*, preferring the squash to all other cultivated plants, but feeding on the cantaloupe or other cucurbits when the squash is not available. This new insect is said to be much more active than the common form and has a later season, appearing 3 weeks later and remaining in the field after the common species has gone into hibernation. In size *A. armigera* is nearly the same as *A. tristis*, but may be readily distinguished from it by a broader prothorax and more prominent angles, the reflected sides of the abdomen showing 4 prominent white marks on the hemelytra, and its armed femora, from which it derives its specific name. The author believes this is a more southern insect and is not liable to become a serious pest in its northern range, although it is capable of severely injuring late crops of all cucurbits. In addition to the localities already mentioned this species is known to occur in Kansas, western Iowa, and Florida.

Scale insects, C. E. CHAMBLISS (*Tennessee Sta. Bul.*, Vol. X, No. 4, pp. 141-151, pl. 1, fig. 1).—Notes are given on the San José and other scale insects which have been observed in Tennessee. At present the San José scale is known to occur in 4 localities in the State. So far as reported its food plants in Tennessee are the apple, peach, plum, pear, apricot, grape, and English walnut. The life history of the scale is given and suggestions made for combating it. From experiments conducted at the station it was learned that two applications of either whale-oil soap or caustic potash soap used at the rate of 2 lbs. per gallon of water is very effective in destroying the scale. Its efficiency is greatly increased on trees having a very rough bark by brushing the trunks and larger limbs.

Descriptions and brief notes on the life history are given of the following additional scale insects: Oyster-shell bark louse (*Mytilaspis pomorum*), scurfy bark louse (*Chionaspis furfurus*), rose scale (*Diaspis rosea*), cottony maple scale (*Pulvinaria innumerabilis*), grape scale (*Aspidiotus uræ*), and peach lecanium (*Lecanium nigrofasciata*).

The bulletin concludes with remarks on the natural enemies of scale insects and gives directions for remedial treatment.

The life history of *Schizoneura lanigera*, W. B. ALWOOD (*Science, n. ser., 8 (1898), No. 195, p. 400*).—In a paper read before Section F of the American Association for the Advancement of Science, the author states that breeding records show that the root and stem forms of this insect can be colonized from root to stem or the reverse. Many of the agamic wingless females at Blacksburg, Virginia, survive the winter exposed on aerial situations. Twelve generations of agamic viviparous females have been observed from May 12 to September 20. At this time winged agamic viviparous females were observed in all colonies examined. Under normal conditions these proved migratory, but in confinement they produced 4 to 6 young, which were sexed individuals. These are small, beakless, and are produced in about the proportion of 2 females to 1 male. After copulation the females lay one egg, which remains dormant during the winter.

From long observations it is concluded that in southern latitudes agamic individuals continue in an unbroken chain and oviparous reproduction plays no important rôle in the life cycle.

The proposed attempt to introduce *Blastophaga psenes* into California, L. O. HOWARD (*Science, n. ser., 8 (1898), No. 195, pp. 399, 400*).—In a paper read before Section F of the American Association for the Advancement of Science at its meeting in August, 1898, the author gives an account of the attempts made to introduce these insects into California. The practice of fig growers in utilizing this insect which inhabits the wild Capri fig is stated, and the belief is expressed that if the *Blastophaga* could be established in California a fig could be grown quite as good as those imported. Capri figs with their insects have been repeatedly imported, but attempts to establish the species have not been very successful. The author believes the time has come to carry on these experiments in a larger way and believes it will be successful.

Elements of apiculture, R. HOMMELL (*L'apiculture par les méthodes simples. Paris: G. Carre and C. Naud, 1898, pp. 338, pls. 6, figs. 102*).

Natural history, anatomy, and physiology of the bee, T. W. COWAN (*Rev. Internat. Apicult., 20 (1898), No. 12, pp. 231-236, figs. 3*).

Beneficial insects (*Jour. Bd. Agr. [London], 5 (1898), No. 3, pp. 326-334, figs. 2*).—Brief notes are given of various ladybirds, syrphus flies, lacewings, and ichneumon flies.

Report of the State entomologist of Norway for 1897, W. SCHÖYEN (*Aarsber. Offent. Foranst. Fremme, 1897, pp. 57-99, ill.*).

Reports of injurious insects in Finland during 1897, E. REUTER (*Landbr. Styr. Meddel, 1898, No. 23, pp. 70*).

Handbook of insects injurious to orchard and bush fruits, E. A. ORMEROD (*London: Simpkin, Marshall & Co., 1898, pp. 286, ill.; rev. in Canad. Ent., 30 (1898),*

No. 12, p. 328).—The different crops treated are apple, cherry, currant, gooseberry, medlar, pear, plum, quince, raspberry, and strawberry. The insects are given with their scientific and popular names, and so far as possible are grouped together. The latest remedies are suggested for the repression of these pests.

A new method of studying underground insects, J. B. SMITH (*Science*, n. ser., 8 (1898), No. 195, pp. 398, 399).—This is an abstract of a paper read before Section F of the American Association for the Advancement of Science at its Boston meeting, in which the author states that plaster Paris thinned makes excellent casts for studying the burrows of underground insects. If properly thinned it will follow the burrow for about 6 ft. underground. In this way satisfactory studies may be made of the burrows of bees, wasps, spiders, and many Coleopterous insects.

The relation of insects to plants and the rôle of extra floral bracts, F. PLATEAU (*Mem. Soc. Zool., France*, 11 (1898), No. 3, pp. 339-368).—This paper is a study of the insect visitors of *Salvia horminum*, *Dianthus barbatus*, and *Hydrangea opuloides*.

Insect enemies of citrus trees, ALLEN, BLUDNO, FROGGATT, and GUTHRIE (*Agr. Gaz. New South Wales*, 9 (1898), No. 10, pp. 1216-1221, pls. 4).—The authors describe and suggest remedies for the following insect pests of citrus fruit trees: Orange butterfly (*Papilio crecthus*), orange borer (*Uracanthus cryptophaga*), *Monolepta rosa*, fruit fly (*Tephritis tryoni*), bronze orange bug (*Oncoscelus sulciventris*), green orange bug (*Rynchocorus* sp.), yellow cross bug (*Mictis sym'olica*), orange aphid (*Siphonophora citrifolii*), fluted scale (*Icerya purchasi*), red scale (*Aspidiotus aurantii*), long scale (*Mytilaspis glomeri*), purple scale (*M. citricola*), white louse (*Chionaspis citri*), brown olive scale (*Lecanium olea*), Indian white wax scale (*Ceroplastis ceriferus*), and orange rust mite (*Phytoptus olecorus*).

New, or little-known, Aleurodidæ, A. L. QUAINANCE (*Canad. Ent.*, 31 (1899), No. 1, pp. 1-4, pl. 1, figs. 7).—The author figures and describes the various phases of a new species to which the name *Aleurodes mori* is given. This insect is said to occur in great abundance on the leaves of mulberry at Tampa, Florida. It also is found in some abundance at Lake City on the leaves of various trees.

Bark beetles of Denmark, E. A. LOEVENDAL (*De Danske Barkbiller. Copenhagen*, 1898; *abs. in Forst. Naturw. Ztschr.*, 7 (1898), No. 12, pp. 448-450).—Illustrated notes are given of about 50 species of Scolytidæ and Platypodidæ and the injury to the trees they attack.

The Cattleya fly, W. H. YOUNG (*Gard. Chron.*, 3. ser., 28 (1899), No. 629, p. 23, fig. 1).—Notes are given of *Isosoma orchidearum*.

Notes on Coccidæ, with descriptions of new species, J. D. TINSLEY (*Canad. Ent.*, 30 (1898), No. 12, pp. 317-320, figs. 2).—*Phenacoccus solenopsis* and *Dactylopius azaleæ* are described and notes given on other species.

New species of Coleoptera of the family Chrysomelidæ, with a short review of the tribe Chlamydiini, M. L. LINELL (*Proc. U. S. Nat. Mus.*, 20 (1898), pp. 473-485).—A monographic review is given of the above and the following new species described: *Megascelis texana*, *Lema longipennis*, *L. jacobina*, *L. lebioides*, *L. coloradensis*, *Chlamys arizonensis*, *Cryptocephalus pubicollis*, *Metachroma reticola*, *Plagioderma purpurea*, *Phyllobrotica nigratarsis*, *Diabrotica nitida*, *Haltica nigrifulva*, and *Crepidodera carinata*.

Two parasites of sugar cane, E. BORDAGE (*Rev. Agr. Reunion*, 2 (1898), No. 9, pp. 400-403).—Notes are given on *Dendroneura sacchari* and *Grapholitha schistaccana*, the grubs of which bore the sugar cane, causing considerable loss.

Notes on insects attacking dried fruit, seeds, etc., W. W. FROGGATT (*Agr. Gaz. New South Wales*, 9 (1898), No. 10, pp. 1103-1105, pl. 1).—Brief notes are given of *Ephestia clutella* in compressed vegetables, *Tenebroides mauretanicus* in wheat, and mites, probably *Tyroglyphus longior*, in linseed meal.

The Hessian fly on timothy, J. FLETCHER (*Canad. Ent.*, 30 (1898), No. 12, p. 301).—The author notes the presence of the puparia of the Hessian fly on specimens of timothy that grew in a badly infested wheat field on Prince Edward Island. The Hessian fly has been reported as attacking timothy in Russia, but the author believes this the first record in America.

Macrolepidoptera of early spring, A. J. NIELSEN (*Ent. Medd.*, 2. ser., 1 (1897), No. 1, pp. 38-43).

Danish Lepidoptera, F. GUDMAN (*Ent. Medd.*, 2. ser., 1 (1897), No. 1, pp. 1-32).

Descriptions of new Noctuids, J. B. SMITH (*Canad. Ent.*, 30 (1898), No. 12, pp. 321-326).—The author describes the following new species: *Eutolype grandis*, *Hadennella larigata*, *H. subjuncta*, *Lathosea ursina*, and *Pleroma bonuscula*. The first species is from Missouri, the others from Colorado.

Revision of the Orthopteran group Melanopli (Acridiidae), with special reference to North American forms, S. H. SCUDDER, *Proc. U. S. Nat. Mus.*, 20 (1898), pp. 1-421, pls. 26).—The following new genera with numerous species are figured and described: *Gymnoscirtetes*, *Netrosoma*, *Phædrotettix*, *Conaleca*, *Barytettix*, *Phaulotettix*, *Cephalotettix*, *Rhabdotettix*, *Cyclocercus*, *Sinaloa*, *Campylacantha*, *Eotettix*, *Æoloplus*, *Phætaliates*, *Pæcilotettix*, *Edaleonotus*, *Asemoplus*, and *Philocleon*.

The earlier phases of Plusia æmula, H. HIRSCHKE (*Verhaull. K. K. Zool. Bot. Gesell. Wien*, 48 (1898), No. 8, pp. 535, 536).—The early stages in the life history of this insect are described. Its food is secured from low growing plants, such as *Hieracium*, *Leontodon*, *Plantago*, clovers, etc.

A new plant louse on tobacco, T. PERGANDE (*Canad. Ent.*, 30 (1898), No. 12, pp. 300, 301).—Technical descriptions are given of *Nectarophora tabaci*, a new plant louse that feeds on tobacco. The insect has been under observation for more than a year, and in addition to tobacco it is said to occur on *Rumex crispus*, *Leucanthemum vulgare*, *Forsythia viridissima*, and on the leaves of the apple, pear, eggplant, and tomato.

Notes on the life history of Protoparce carolina, W. B. ALWOOD (*Science*, n. ser., 8 (1898), No. 195, p. 400).—The author states that in the vicinity of Blacksburg, Virginia, this species shows a tendency to be double brooded. The earliest moths appear June 7-12, oviposition begins June 20, the larvæ molt four times at intervals of about 4 days, become full-fed in 20 to 21 days, and enter the soil for pupation. A small part of the brood issues as adults the first year, but the greater part are single brooded and appear as adults in July after passing the winter as pupæ.

Classification of the suborder Phytophaga, W. H. ASHMEAD (*Canad. Ent.*, 30 (1898), No. 12, pp. 305-316).—This is the concluding paper on this subject and deals with the families Tenthredinidæ and Cimbicidæ.

Sphærococcus in Massachusetts, T. D. A. COCKERELL and G. B. KING (*Canad. Ent.*, 30 (1898), No. 12, p. 326).—*Sphærococcus sylvestris* n. sp. is described on the white oak in Massachusetts. It is closely related to *S. parrus*, but may be distinguished by its better-developed antennæ.

The life history of Tortrix resinella, M. BÜSGEN (*Allg. Forst u. Jagd Ztg.*, 74 (1898), No. 12, pp. 380-383).

American leaf hoppers of the subfamily Typhlocybinae, C. P. GILLETTE (*Proc. U. S. Nat. Mus.*, 20 (1898), pp. 709-773).—A monographic review is given of the above and the following new species described: *Alebra currilinea*, *A. bifasciata*, *A. trimaculata*, *A. robusta*, *A. dorsalis*, *A. fumida*, *Dicranocura maculata*, *D. eructata*, *D. unipuncta*, *D. communis*, *D. quadrivittata*, *Empoasca trifasciata*, *E. liringstonii*, *E. unicolor*, *E. splendida*, *E. albolinea*, *E. denticula*, *E. pergandei*, *E. incisa*, *E. atrolabes*, *E. mexicana*, *E. radiata*, *E. robusta*, *E. pallida*, *E. snowi*, *E. alboncra*, *E. tumida*, *Eupteryx vanduzeei*, *E. flavoscuta*, *Typhlocyba bipunctata*, *T. tunicarubra*, *T. hartii*, *T. rubroscuta*, *T. illinoensis*, *T. dentata*, and *T. crevecœuri*.

Colorado's worst insect pests and their remedies, C. P. GILLETTE (*Colorado Sta. Bul.* 47, pp. 64, figs. 54).—The author gives popular descriptions and suggests methods for the destruction of the principal insect enemies of the apple, pear, plum, peach, and cherry trees; small fruits; roses; shade trees; farm and garden crops; grain insects and household pests. A number of insecticides are described, their methods of preparation and use being given in considerable detail.

The Coccidæ of Kansas, S. J. HUNTER (*Kansas Univ. Quart.*, 8 (1899), No. 1, pp. 1-15, pl. 1).—Critical notes and descriptions of new species.

Odor of the San José scale, F. M. WEBSTER (*Canad. Ent.*, 31 (1899), No. 1, p. 4).—Attention is called to the odor which is associated with *Aspidiotus perniciosus* by which, in cases of considerable abundance, the scale can be detected at a considerable distance. When the air is quiet it is often possible to detect the presence of a badly infested tree at a distance of a yard or more. The author comments on the possession of this odor and states that possibly in its native home this may attract insects and afford means of diffusion which are not present in this country.

A new danger to fruit growers, L. R. TAFT (*Michigan Sta. Spec. Bul.* 7, pp. 3).—Attention is directed to the San José scale and the growers are warned against its attacks.

Summer treatment for the San José scale, W. B. ALWOOD (*Virginia Sta. Bul.* 74, pp. 28-34, figs. 3).—This records data obtained in the use of pure kerosene against the San José scale since the publication of Bulletin 72 of the station (E. S. R., 9, p. 1067). Instances are noted in which kerosene proved very injurious to the trees, but in many cases no serious injury was noted, even when trees were in flower at the time of spraying. In regard to the use of kerosene the author says:

"The foregoing abstracts and unpublished matter in the records of the work now in progress show that pure kerosene can be safely used upon all our fruit trees in the dormant season and with proper precautions during the growing season also. The chief point to be observed in its application is the proper atomization of the kerosene. Unless it be applied in a finely atomized condition, and in quantity so as to just moisten the parts of the plant there is danger. The skill and judgment necessary to insure safety in this work are not such as to preclude the use of kerosene by fruit growers, hence in the light of the above and other unpublished experiments, I recommend it as a summer treatment for San José scale. I believe it to be the treatment *par excellence*, as in every case where I have used it on this scale it has destroyed them with great certainty. It is too soon to make an absolute statement as to the degree of efficacy, but the experiments now under way will furnish much data on this point by the end of the season."

Three forms of apparatus for spraying kerosene are figured and briefly discussed. Some form of blast atomizer is thought to be best.

Hydrocyanic-acid gas fumigation, A. F. WOODS (*Florists' Exchange*, 10 (1898), No. 49, p. 1146).—Reports on tests made to observe the effect of weak doses of hydrocyanic-acid gas for long periods on greenhouse plants in large houses. It was found that any dose weaker than 0.15 gm. of 98 per cent cyanid per cubic foot of space in the house for 20 minutes was ineffectual.

Fumigation of fruit with hydrocyanic acid, F. B. GUTHRIE (*Agr. Gaz. New South Wales*, 9 (1898), No. 10, p. 1191).—Oranges, lemons, and apples were placed in a small chamber and treated for 3 hours with vapor of hydrocyanic gas. After exposing the fruit in the open air for half an hour no trace of the acid could be detected in the flesh or outer skin of the fruit by smell, taste, or chemical examination. No live scale remained.

Legislation for the suppression of the San José scale, W. B. ALWOOD (*Virginia Sta. Bul.* 74, pp. 21-28).—The law of Virginia relating to the San José scale is given, together with comments by the author of the bulletin. The lines of work to be followed under the law are pointed out.

FOODS—ANIMAL PRODUCTION.

On the relative digestibility of white and brown [whole wheat] bread, T. L. BRUNTON and F. W. TUNNICLIFFE (*St. Bartholomew's Hospital Rpts.*, 33 (1897), pp. 157-168).—The authors report an extended

study of the composition and digestibility of white and whole-wheat bread. The composition of the two sorts of bread was as follows:

Composition of white and whole-wheat bread.

	White bread.	Whole- wheat bread.
	<i>Per cent.</i>	<i>Per cent.</i>
Water	39.10	40.18
Dry substance	60.90	59.82
Total ash59	1.88
Phosphoric acid16	.51
Soluble matter	4.73	7.54
Nitrogen	1.32	1.25
Albumen, calculated from nitrogen	8.25	7.87
Pure albumen	7.34	7.86
Soluble nitrogenous matter61	.73
Starch and saccharine matters, etc.	51.85	49.44
Starch	38.45	39.18
Sugar (maltose)	1.19	1.77
Dextrin84	.71
Cellulose24	1.06
Fat21	.63
Acidity (lactic acid)19	.29
Loss of water in fifteen days	9.23

Artificial digestion experiments were made with mixed saliva and Benger's liquor pancreaticus and liquor pepticus. The principal deductions from the experiments, which are discussed in detail, follow:

"From the experiments we are justified in concluding that the higher nutritive value which we might, upon pure chemical grounds, ascribe to brown bread, can not, with the single exception of fats and mineral constituents, be maintained from the physiological side. On the other hand, distinctly less of the nutritive materials actually get into the blood in the case of brown than of white bread. . . .

"White bread is, weight for weight, more nutritious than brown. Therefore it appears the preference given by operators in large towns for white bread has, to a certain extent, a sound physiological basis.

"In the case of people with irritable intestines, white bread is to be preferred to brown.

"In the case of people with sluggish intestines, brown bread is preferable to white, as it tends to maintain regular peristaltic action, and insure regular evacuation of the bowels, with all its attendant advantages.

"In cases where the proportion of mineral ingredients, and especially of lime salts, in other articles of food or drink is insufficient, brown bread is preferable to white. . . .

"If the dietary is insufficient in fat, or if the patient is unable readily to digest fat in other forms, brown bread may possibly be preferable to white."

The use of molasses in feeding animals, D. DICKSON and L. MALPEAUX (*Ann. Agron.*, 24 (1898), No. 8, pp. 353-381).—Experiments on the value of molasses as part of a ration are reported with sheep, pigs, steers, milch cows, and horses. The principal conclusions follow: When molasses formed part of the ration of sheep, pigs, and steers the gains in live weight were rapid. When molasses was fed to milch cows the total milk yield and the amount of fat and milk sugar in the milk was increased. The increase is not regarded as sufficient to warrant the conclusion that molasses is a suitable food for milch cows. Molasses is regarded as an excellent food for horses. It was readily eaten and vigor and weight were maintained when it was added to the

ration. Molasses may be advantageously employed for rendering inferior hay or fodder more palatable.

Bullock-feeding experiment, T. B. WOOD (*Cambridge and Counties Agr. Education Scheme, Field and Feeding Experiments, Rpt. 1897, pp. 44-52*).—Brief reference is made to feeding experiments with sheep and steers carried on in previous years at Whitlingham, Norfolk. In the winter of 1896-97 a test was made with 4 lots of 5 steers each, to compare linseed cake and the following grain mixtures: Linseed cake and common cotton-seed cake; decorticated cotton-seed cake and maize meal; and decorticated cotton-seed cake, common cotton-seed cake, maize meal, and dried grains. In addition to the grain the steers were given 10 lbs. of mixed chaff and 112 lbs. of roots per head daily. The average weekly gains per head of the 4 lots was 16.7 lbs., 13.9 lbs., 14.0 lbs., and 15.2 lbs. The net profits were from \$3.60 to \$4.86 per head. Making allowance for the manurial value of the food, linseed cake gave slightly the best results. Few details of this test are given.

In 1897-98 a similar test was made with 4 lots of 5 steers each. Lot 1 was fed linseed cake; lot 2, linseed cake and common cotton-seed cake, 1:1; lot 3, decorticated cotton-seed cake and dried brewers' grains, 1:1; and lot 4, linseed cake, common cotton-seed cake, and maize meal, 1:1:1. At the beginning of the test the steers were fed per head daily 6 lbs. of the grain ration. After about a month the ration was increased to 8 lbs. and later to 10 lbs. In addition the steers were fed 10 lbs. cut (chaffed) hay and straw mixed and 112 lbs. of roots per head daily. The test began December 13 and continued until the steers were judged ready for slaughtering. One steer from each lot was sold and slaughtered March 15, March 16, April 18, April 25, and May 3. The average weekly gain per head of the 4 lots was 11.9 lbs., 10.6 lbs., 9.3 lbs., and 10.5 lbs., respectively. The gains of the steers of the different lots and the cost of gains are discussed in detail, the results being compared with the test made in the previous year.

"Summarizing the 2 years' results, the 2 experiments have agreed very well, and it appears clear that linseed cake alone is the most profitable food to purchase for fattening steers, though it has been very closely followed in each experiment by the mixture of linseed cake, common cotton cake, and dried grains, with or without maize meal. Linseed cake and common cotton cake mixed have always paid the least, but it is worthy of notice that the steers eating this mixture have always started well, and have only lost ground later in the period of feeding. This suggests that in future experiments one lot should be started on linseed cake and common cotton cake, half and half, for the first month, after which the proportion of linseed cake should be raised, until the steers finished up the last month on linseed cake only. This ration would probably compare favorably from an economical point of view with cake alone all the time."

Rape for lambs, J. A. CRAIG (*Wisconsin Sta. Rpt. 1897, pp. 72-79, fig. 1*).—The author quotes at some length experiments on the value of rape for fattening lambs, which were previously reported (E. S. R., 8, p. 327). The value of rape for lambs previous to fattening was tested in 1896 with 2 lots of 48 lambs. The lambs were dipped and tagged, and after a preliminary period of 2 weeks the test proper began October 12. It was divided into 2 periods of 4 and 12 weeks. Lot 1 was

fed rape and lot 2 was given the range of a blue-grass pasture. In addition both lots were fed a mixture of peas and corn 1:1. At the beginning of the test lot 1 weighed 3,022.5 lbs. and lot 2, 3,232.5 lbs. The gains made by the 2 lots were 501 and 325 lbs. respectively. Lot 2 was fed the rape from 0.64 acre. Each lot consumed 878 lbs. of the grain mixture. During the second period both lots were fed in sheds, and given similar rations, consisting of hay and a mixture of corn and peas 1:1, the object being to compare the influence of the previous pasturing on fattening. Lot 1 gained 952 lbs. and lot 2, 858 lbs. Each lot consumed 4,084 lbs. of grain. Lot 1 consumed 2,488 lbs. of hay and lot 2 2,703.5, a difference of 215.5 lbs. in favor of lot 1.

"From the results it will be seen that when the 2 lots were put in pens and fed similar rations, lot 1 that had rape instead of pasture made a greater gain than the other lot, and they also ate less hay, thus showing the beneficial influence of pasturing lambs on rape in the fall previous to fattening them."

Grain for lambs before weaning, J. A. CRAIG (Wisconsin Sta. Rpt. 1897, pp. 37-41).—The author quotes earlier work (E. S. R., 8, p. 714), and reports additional tests of the value of grain before and after weaning. In 1896 a test was made of 4 lots of 6 lambs to compare corn meal, oats, bran, and cracked peas. The test began April 14 and covered 12 weeks before weaning. Three ewes ran with the lambs in each lot and were given the same rations as the lambs mentioned below. The financial statement is based on oats at 20 cts., corn at 30 cts., and peas at 45 cts. per bushel, and bran at \$13 per ton. The results are summarized in the following table:

Results of feeding grain to lambs before weaning in 1896.

Lot.	Food.	Weight at beginning.	Total gain.	Food eaten per pound of gain.	Cost of food per pound of gain.
		<i>Pounds.</i>	<i>Pounds.</i>	<i>Pound.</i>	<i>Cent.</i>
1	Ground corn	153.0	297.5	0.19	0.10
2	Whole oats.....	145.5	298.5	.68	.40
3	Bran	144.0	307.5	.20	.12
4	Cracked peas	145.5	298.0	.75	.52

In 1897 a test was made with 4 lots of 6 Shropshire grade lambs, 3 ewes running with each lot. The test covered the 10 weeks previous to weaning. The conditions of the experiment were the same as in the preceding test. The results were as follows:

Results of feeding grain to lambs before weaning in 1897.

Lot.	Food.	Weight at beginning.	Total gain.	Food eaten per pound of gain.	Cost of food per pound of gain.
		<i>Pounds.</i>	<i>Pounds.</i>	<i>Pound.</i>	<i>Cent.</i>
1	Ground corn	314.0	214.5	0.55	0.27
2	Whole oats.....	316.0	211.5	.51	.30
3	Bran	299.5	181.0	.53	.31
4	Cracked peas	307.0	188.0	.69	.48

From these tests and that previously reported the general deductions are drawn that—

“The ground corn gave the best results as far as cost of gain is concerned, and next to it ranks bran, while oats and peas are shown to be of equal value. . . . The trials show that for feeding lambs when they are suckling their dams these foods should be chosen in the following order: First, ground corn; second, bran; third, oats or cracked peas.”

Grain mixture for lambs before and after weaning, J. A. CRAIG (*Wisconsin Sta. Rpt. 1897, pp. 42-44*).—The comparative value of corn and a mixture of corn with other grains was tested with 15 lambs before and after weaning. They were divided into 3 lots of 5 each. There were 3 ewes with the lambs in each lot. Lot 1 was fed ground corn, lot 2 corn and oats, and lot 3 ground corn and cracked peas. The lambs were fed all the grain they would eat morning and evening, and during the day were with their dams on ordinary blue-grass pasture. The test covered 8 weeks before and 8 weeks after weaning. The weight of the lots at the beginning of the test was as follows: Lot 1, 291.5 lbs.; lot 2, 299.5 lbs.; and lot 3, 288 lbs. In 8 weeks the 3 lots had gained 139, 139.5, and 139 lbs., consuming 0.26, 0.31, and 0.42 lb. of grain, respectively, per pound of gain. In each case the corresponding cost of gain was 0.13, 0.17, and 0.24 ct. During 8 weeks immediately after weaning lot 1 gained 95, lot 2, 92.5, and lot 3, 98 lbs., consuming 0.13, 0.14, and 0.13 lb. of grain per pound of gain, respectively, the cost of gain being 0.6, 0.7, and 0.7 ct. per pound.

“The outcome of this trial still maintains the position of ground corn as a food for lambs, though the results are practically the same from the lambs in all of the lots. The lot getting the corn and peas gained slightly the most, and they ate more grain than the others, but in respect to the cost of the gain the ground corn maintains its position.

“The mixture of corn and peas, however, seems to be a ration that the lambs relish as they grow older, but previous to weaning none of these mixtures seem to give as satisfactory results as the ground corn. It is a fact, however, that in feeding such a ration as ground corn alone there is likely to be more sickness among the lambs than if they have a mixed ration. Aside from this the addition of oats or peas to the ration of unground corn produced no appreciable benefit, while it increased the cost in every instance.”

Lambs for early spring market, J. A. CRAIG (*Wisconsin Sta. Rpt. 1897, pp. 45-49, figs. 1*).—The lambs raised at the station are mostly a cross of a pure-bred Dorset ram on Shropshire grade ewes. There are also some second-cross lambs; that is, lambs from a crossing of a pure-bred Dorset ram on the cross-bred ewes mentioned above. The author gives in tabular form the number and cross of the ewe, date of service, date of lambing, number of lambs, date when sold, and the weight and value of the lambs in the station flock.

“From our experience in trying to establish a flock for breeding early lambs, we can say that a reasonable degree of success may be attained as soon as the first-cross ewes are ready to be bred, but it is equally clear that a greater certainty of breeding the ewes early exists where the ewes are the second cross of the Dorset on native sheep.”

Experiments in sheep fattening, J. GRUDE (*Aarsber. Offent. Foranst. Fremme, 1897, pp. 282-290*).—The tests were conducted on the same general plan as the earlier experiments carried on by the author with government aid (E. S. R., 5, p. 919; 8, p. 154; 9, p. 1075). The following table shows the principal results:

Results of sheep-feeding experiments, 1897.

	Number of animals.	Average age.	Average length of fattening period.	Feed per day per 1,000 kg. live weight.				Live weight.		Increase in live weight.
				Hay.	Tur-nips.	Linseed oilcake.	Oats.	At beginning.	At end.	
		Years.	Days.	Kg.	Kg.	Kg.	Kg.	Kg.	Kg.	Per ct.

—F. W. WOLL.

Establishing a flock of mutton sheep, J. A. CRAIG (*Wisconsin Sta. Rpt. 1897, pp. 50-55, figs. 3*).—The author discusses the requirements for a flock of mutton sheep. The most important considerations in his opinion are good rams and ewes that are deep milkers and suckle their lambs well and have the densest fleeces for their own protection.

"It matters little if a ewe is not as nicely rounded in form as she might be. If she is a good milker, she deserves the premier position in the flock. . . . The feeding of the ewe lambs that are to furnish the new material for the flock should be liberal in every sense of the word. Feed them liberally on oats and see that they get the best pasturage that it is possible to secure for them, and it will be found surprising how lusty they will grow during the first 9 months of their lives."

Uniformity in the lambs raised is deemed an important requisite.

"To secure this it should be an axiom for every flock master to never sell or dispose of a ram that proves to be a valuable breeder as well as a getter of superior lambs. Such a ram should be permanently retained at the head of the flock, and bred to the same ewes year after year as long as it is possible to do so."

Whole corn compared with corn meal for pig feeding, W. A. HENRY (*Wisconsin Sta. Rpt. 1897, pp. 29-36*).—The author quotes in some detail 2 experiments in 1896 on this subject (E. S. R., 9, p. 580), and reports 2 additional experiments made in 1897. The first trial in 1897 was with 2 lots of 9 Poland China-Chester White pigs each. They were all straight bodied, strong boned, and well built, with vigorous constitutions. They had been pastured on rape or grass and given grain, and were in rather high condition at the beginning of the trial. Lot 1 was fed a ration consisting of shelled corn and wheat middlings 2:1. The shelled corn was fed in a trough and when consumed the wheat middlings was fed mixed with water. Lot 2 was fed corn meal and wheat middlings 2:1. The test covered 12 weeks. Lot 1 weighed 1,907

lbs. at the beginning of the trial and gained 984 lbs., consuming 4.42 lbs. of grain per pound of gain. Lot 2 weighed 1,886 lbs. at the beginning of the test, gained 1,348 lbs., and consumed 5.01 lbs. of grain per pound of gain. In the author's opinion the amount of feed required per pound of gain is reasonable considering the good condition of the pigs at the beginning of the trial.

The second test was made with 2 lots of 7 pure-bred Poland Chinas and cross-bred Poland China Berkshires. "They were of fine bone with round bodies and much more delicate than the preceding lot. They showed in strong contrast with those of the first trial the difference between pigs of good bone and constitution and those too much refined by high breeding." These pigs had likewise been pastured on rape or grass before beginning the test, which covered 9 weeks. In other respects the conditions were the same as in the preceding trial. Lot 1 weighed 1,281 lbs. at the beginning of the trial and gained 552 lbs., consuming 4.62 lbs. of grain per pound of gain. Lot 2 weighed 1,383 lbs. at the beginning of the trial and gained 576 lbs., consuming 4.24 lbs. of grain per pound of gain. The gains made at different periods of the test are discussed and the results of these trials are compared with those of earlier tests.

"The gains were greatest during the first weeks of the trial and lightest during the last weeks. On the contrary, more feed was eaten during the last weeks of the trial than in the beginning. Coming to the feed required per pound of gain, the results obtained in the earlier stages stand in strong contrast with those obtained near the close. For the first week 3.62 lbs. of feed made 1 lb. of gain, while in the twelfth week 5.98 lbs. were required.

"Grouping the results into four-week periods in order to secure better averages . . . we see that during the first period of 4 weeks, 4.18 lbs. of feed made 1 lb. of gain; during the second four-weeks period 4.61 lbs. were required; and during the last four weeks 5.59 lbs. of feed were required per pound of gain."

Data concerning sow and pigs at farrowing time, W. A. HENRY (*Wisconsin Sta. Rpt. 1897, pp. 8, 9*).—A number of observations were made in the spring of 1897 on pure-bred Poland China and Berkshire pigs or crosses of these breeds, and upon cross-bred Poland Chinas and Chester Whites. The sows ranged from 1 to 4 years in age and from 240 to 577 lbs. in weight. They were weighed several hours before and several hours after farrowing and the pigs were also weighed. The average weight of the sows before farrowing was 382.1 lbs. and after farrowing 359 lbs. The average weight of the afterbirth was 4.01 lbs.

"The litters averaged 16.7 lbs. each, the individual pigs ranging in weight from 1.3 to 3.1 lbs., the average being 2.2 lbs. In general, the individual pigs in large litters are somewhat smaller than those of small litters.

"Frequently in a litter of pigs there is one member much weaker than the others, and this is styled the 'runt' or 'teatman.' It is sometimes spoken of as the last pig farrowed, this occurrence seeming in some unknown way to mark its inferiority. [The observations made showed that] the last pig farrowed was not necessarily of lighter weight than the others, and the observer noted no weakness or other mark indicating inferiority in any way."

The cost of feeding pigs before and after weaning, W. A. HENRY (*Wisconsin Sta. Rpt. 1897, pp. 20-28*).—Tests were made with 5 sows and their litters, to compare the cost of feeding before and after weaning. There were 6 pigs with sow 1, 6 with sow 2, 7 with sow 3, 9 with sow 4, and 12 with sow 5. All the lots were fed equal parts by weight of a mixture of corn meal, middlings, and skim milk 1:1:4. The milk was generally sour. Water was supplied in addition. When very young the pigs were given no food except milk supplied by the sows. As they increased in size they were encouraged to eat the ration mentioned above, which was placed before them in a separate trough 3 times daily. The pigs were weaned when 70 days old, and the feeding continued for 49 days after weaning, the pigs being fed all they would eat without waste. On the other hand, the sows, having gained in weight while suckling the pigs, were given a limited quantity of food, in order that they might not make too much gain. The tests are reported in detail in tabular form. The results are summarized in the following table, which shows the food required per pound of gain by both sows and pigs before weaning and by each after weaning:

Average of results with sows and pigs before and after weaning.

	Feed required per pound of gain.	
	Meal.	Milk.
Sows and pigs before weaning.....	Pounds. 2.37	Pounds. 4.75
Pigs after weaning.....	2.88	5.76
Sows after weaning.....	7.10	14.20

On the supposition that 6 lbs. of separator skim milk is the equivalent of 1 lb. of meal, the author calculates that the sows and pigs before weaning required food equivalent to 3.16 lbs. of meal per pound of gain, and the pigs after weaning the equivalent of 3.84 lbs. of meal.

“In these figures we have another illustration of how much more economical young pigs are than more mature animals in the feed required for a given gain. When these same pigs have reached a weight of 300 lbs., about 500 lbs. of grain will be required for 100 lbs. of gain.

“A large amount of feed was required by the sows for 100 lbs. of gain after their pigs had been weaned; the explanation of this is simple. These sows had usually gained in weight while suckling their pigs and were therefore in good flesh. Being required for future breeders, we did not wish them to become too fat, a condition which they would readily attain, had sufficient feed been supplied. These figures afford an excellent illustration of how unprofitable it is to supply animals with less feed than they can readily consume when gain in weight is the end desired. These sows require nearly three times as much feed for 100 lbs. of gain as did their pigs which had just been weaned from them. This is because the herdsman gave them a very limited quantity of nutrients, only about what they required for maintenance, his object being not to allow them to materially gain in flesh.”

Peat molasses for horses, H. GOLDSMITH (*Ugeskr. Landm., 43 (1898), No. 23-24, pp. 291, 292, 306-309*).—The peat molasses fed in this experiment was manufactured from beet molasses and dry peat in the proper-

tion of 4:1. Chemical analysis by V. Stein showed it to contain: Water, 23.80 per cent; protein, 9.31 per cent; fat, 0.23 per cent; carbohydrates, 52.60 per cent (sugar, 40.1 per cent); crude fiber, 3.75 per cent; ash, 10.31 per cent.

Twenty street-car horses were included in the experiment, which was continued for about 4½ months (December 20–May 2). The regular grain ration of the horses consisted of 11 lbs. of oats, 5.5 lbs. corn, 1.65 lbs. wheat bran, 0.55 lbs. rye bread. For 15 of the horses 3.3 lbs. of this mixture was replaced by 3.3 lbs. of peat molasses, and after 2 months 2.2 lbs. were again replaced by 2.2 lbs. of peat molasses. The remaining 5 horses formed a control lot and were fed the regular grain ration during the entire experiment. The health of the horses and their capacity for work were satisfactory throughout the test. The average weight of the horses fed peat molasses at the beginning of the test was 1,226.5 lbs.: at the end of the first period there was a loss of 25.3 lbs.; at the end of the second period a gain of 8.8 lbs. Considering the experiment as a whole there was a loss of 23.1 lbs. The average weight of the horses fed grain at the beginning was 1,298 lbs.; at the end of the first period there was a loss of 14.3 lbs.; at the end of the second period there was a loss of 16.5 lbs. During the whole test there was a loss of 34.1 lbs.

While 3.3 lbs. of peat molasses could not quite take the place of 3.3 lbs. of grain feed in the experiment, it will be noticed that 2.2 lbs. of the molasses feed under the conditions present had a higher nutritive effect than the same weight of grain feed. Considering the average results obtained for both periods the peat molasses proved somewhat superior to the oats and corn. The experiment indicates that a few pounds of peat molasses may be fed daily to horses with advantage, if this feed is cheaper, pound for pound, than common concentrated horse feeds. The decrease in weight of the experimental horses is in accordance with general experience, as horses regularly fall off in weight during the spring (according to the author. about 16.5 lbs. per head).—F. W. WOLL.

The distribution of gluten and its constituents in the starch layer of wheat, E. FLEURENT (*Compt. Rend. Acad. Sci. Paris*, 126 (1898), No. 23, pp. 1592–1595).—The gluten in the flour at different stages of grinding and the amount of glutenin and gliadin in the gluten are reported in several sorts of wheat. The results, in the author's opinion, show that the gluten content and the composition of the gluten varies in different varieties of wheat and in the products obtained from the same wheat at different stages of grinding. The quantity of gluten increases from the center toward the periphery of the starch layer and the gluten contains a higher percentage of glutenin as it approaches the interior of the grain.

Nuts as food in foreign countries (*U. S. Consular Rpts.*, 1898, No. 219, pp. 537–548).—These articles, prepared by the consuls to the various countries, describe the nuts used as food in France, Italy, Korea, and Syria. In France these were chestnuts, almonds, and peanuts; in Italy, almonds, filberts, chestnuts, pistachios, walnuts, and pine nuts; in Korea, chestnuts, walnuts, pine nuts, peanuts, and jinko nuts; in Syria, chestnuts, filberts, pine nuts, pistachios, and walnuts. In several cases statistics of the amount consumed are given together with methods of cultivation, etc.

The composition of Ohio wines, A. W. SMITH and N. PARKS (*Jour. Amer. Chem. Soc.*, 20 (1898), No. 11, pp. 878-882).—Analyses are given of wine made by the authors from 12 varieties of grapes grown in Ohio, and of a number of typical samples of wines sold in northern Ohio. The Ohio wines were 1 year old, except 2 samples which were 2 years old. The results are compared with European analyses and standards, and the application of the results in determining cases of adulteration is pointed out.

Michigan Dairy and Food Commission Bulletin 40 (pp. 43).—A report is given of the examination of a considerable number of samples of spices, imitation fruit jelly, oleomargarin, etc., together with a résumé of the Dairy and Food Commission's operations for the 6 months ending December 31, 1898.

Publications of the institute of hygiene of the University of Padua (*Pubblicazioni Dell' Istituto D'Igiene Della R. Università Di Padova. Padova: P. Prosperini, 1898, p. 344, maps 2*).—This volume (which is made up of separates with an introduction) contains the investigations which have been conducted by Prof. A. Serafini, or by his students under his direction. Some of these have already been noted in the Record (E. S. R., 9, pp. 265, 266).

Rules for the management of the Bengali Institute Hostel and scale of dietary studies for each student, F. RAYMOND (*Ann. Rpt. Cir. Vet. Dept. [Bengal], 1897-98, Append. 21-22, pp. 14-16*).—The kinds and amount of food consumed per man per day in the students' boarding club and its cost are briefly recorded.

Annual report of the live stock breeders' associations (*Rpts. Live Stock Assoces. Province of Ontario, 1897-98, pp. 142*).—This contains the usual addresses and reports and, in addition, the following papers: Tuberculosis in cattle, D. Metrae; The requirements of the home and foreign mutton and wool markets, M. Levering; Short-horn prospects, R. Gibson; Broad-minded breeders, W. Linton; Beef breeds and their value, J. I. Hobson; Care and application of manure, J. Yuill; and The Ayrshire and its uses, J. C. Smith.

A digest of metabolism experiments, W. O. ATWATER and C. F. LANGWORTHY (*U. S. Dept. Agr., Office of Experiment Stations Bul. 45, rev. ed., pp. 434*).—A number of errors in the figures in the tables have been corrected.

Analyses of cakes used in bullock-feeding experiments, T. B. WOOD (*Cambridge and Counties Agr. Education Scheme, Field and Feeding Expts., Rpt. 1897, p. 53*).—Analyses of the composition of the cakes used in steer feeding experiments stated above (p. 773), are reported.

The fattening of cattle, J. W. ROBERTSON (*Rpt. Comr. Agr. and Dairying, Canada, 1897, pt. 4, pp. 23-30*).—These tests have been noted from another source (E. S. R., 6, p. 450; 8, p. 916).

Calf raising, J. MASWERSIT (*Fühling's Landw. Ztg., 47 (1898), No. 24, pp. 918-920*).—The author reports the successful use of starch and skim milk as a food for calves.

Experiments to determine the effect of pea meal and sunflower-seed cake on the quality of fat, flesh, and wool of sheep, RAMM (*Deut. Landw. Presse, 25 (1898), No. 80, p. 855; 81, p. 864, figs.; 82, pp. 875, 876; 84, pp. 895, 896*).—Tests were made with 4 lots of 3 sheep each. Lots 1 and 3 were Merinos; lots 2 and 4, English sheep. Lots 1 and 2 were given sunflower-seed cake and lots 3 and 4, pea meal. The principal conclusions follow:

The Merino sheep made 10 per cent higher gains than the English sheep. Disregarding the belly fat, the results of slaughter tests of the breeds were about the same. The English sheep, however, had more belly fat and, in general, fatter carcasses. The solidifying point of the Merino fat was several degrees lower than that of the fat in the English sheep. The Merino sheep produced more wool than the others; the wool contained about twice as much wool fat; and the melting point of the wool fat was about $2\frac{1}{2}$ per cent higher than that of the wool of the English sheep. The gains made with pea meal were about 2.2 per cent better, and the results of slaughter tests were also about 6.54 per cent better than in the case of the sunflower-seed cake. The sheep fed pea meal showed more belly fat, the flesh contained more dry matter, and more nitrogen. The fat had a much lower iodine value. The sheep fed sunflower-seed cake weighed more shorn and the wool contained more fat. The melting point of the wool fat was, however, 4.2 per cent lower.

Molasses as a feed for swine, G. FAYE and E. FREDERIKSEN (*Vgeskr. Landm.*, 43 (1898), No. 11, pp. 134-139).—Forty pigs were divided into 2 lots of 20 each, one lot was fed Indian corn and the other barley. In each case molasses feed was substituted for one-third of the grain ration of part of the pigs.

The test covered 140 days. The results are expressed in full in tabular form. The test indicates that beet molasses when it is not fed too heavily, is an economical food for swine, its feeding value being equal to about three-fourths of that of grain feeds, pound for pound.—F. W. WOLL.

Rape for swine, J. A. CRAIG (*Wisconsin Sta. Rpt.* 1897, pp. 80, 81).—The tests were reported in a previous publication (E. S. R., 9, p. 374).

Concerning horse raising in Denmark, S. VON NATHUSIUS (*Fühling's Landw. Ztg.*, 47 (1898), No. 22, pp. 834-840; 23, pp. 865-870).—The author visited Denmark and gives his opinion of horses and horse raising in that country in some detail.

The duration of a horse's life and the limits of his usefulness for work and breeding purposes, ZÜRN (*Fühling's Landw. Ztg.*, 47 (1898), No. 24, pp. 929-931).—The author quotes many instances which are believed to be authentic of horses which have lived to an extreme age and many of them have been useful as draft animals and for breeding purposes.

DAIRY FARMING—DAIRYING.

Variations in milk and milk production, E. DAVENPORT and W. J. FRASER (*Illinois Sta. Bul.* 51, pp. 77-104, *dgm.* 1).—This is a record for 2 high-grade Jerseys, 2 registered Holsteins, and 1 high-grade Holstein. All were given similar care and feed. The fat was determined by the Babcock test and the solids-not-fat were calculated from the lactometer reading. The data were recorded for each of the 5 cows separately for each milking. A complete record for all 5 cows for 1 month and of 1 cow for 10 months is given in tables. The records of all the cows for 3 months were compiled and the results are presented and discussed. The yield and quality of the milk at the beginning and near the close of the period of lactation was also considered. A diagram is given showing the daily feed consumed and the yield of milk and fat for 2 cows for a period of 4 months. The authors' deductions from the record are as follows:

“The yield of milk from different cows under the same conditions differs greatly, and that from the same cow varies widely from day to day.

“The composition of milk is highly variable; the ratio of fat to other solids, and that of solids to water, is not constant as between different cows or for the same cow on successive days.

“The percentage of fat, or of other solids, is not always highest in the smaller yields, but cows that give milk with a high percentage of solids generally show a low total yield.

“Fat is the most variable constituent of milk, and its variations are independent of those of the other solids; therefore the yield of milk is a better index of the other solids than it is of the fat.

“As regards the first and last milk drawn, the proportion of solids-not-fat is higher in the first, but the proportion of fat is decidedly greater in the last.

“When the milking periods are unequal the longer period will generally, though not always, give the larger yield of milk, of fat, and of solids-not-fat; but the difference in yield does not correspond to the difference in time; that is, the secretion calculated per hour is greater during the shorter period.

"Neither daytime nor nighttime is shown to be superior as a milk-producing period.

"Different cows differ in their power to make milk from food, and the same cow varies in this respect from time to time.

"It pays to select the individual according to her power to manufacture milk from food, and according to the character of the product.

"Aside from the influence of food or environment each animal exhibits individual variations of her own, and such variations tend to show something like periodicity in the separate functional activities of the animal body."

Test of the Guernsey cow Suke of Rosendale (6520 G. H. B.)
 F. W. WOLL (*Wisconsin Sta. Rpt. 1897, pp. 153-160, fig. 1*).—A test of this cow for one week just after calving by one of the owners "shows a total production of 189.7 lbs. of milk and 14.98 lbs. of butter fat, making the average fat content of the milk produced during the week 7.90 per cent." For the purpose of studying the quality of the milk during the progress of lactation, samples were sent to the station on the 20th to 21st of each month during the winter, spring, and summer until the cow was dried off. The methods of analysis employed are described and the results of this study are tabulated, together with a summary of the yield and butter fat during 4 previous periods of lactation. The milk at no time during the test equaled in fat content that shown in the preliminary test of one week, indicating "that the high percentages of fat in the milk shortly after calving were due to abnormal conditions in the cow at the time." During the 285 days of the test the cow produced 5,490.7 lbs. of milk with an average fat content of 5.78 per cent, the total yield of fat being 317.28 lbs., an average of 1.11 lbs. per day.

A new proteid constituent of milk, A. WRÓBLEWSKI (*Ztschr. Physiol. Chem., 26 (1898), No. 3-4, pp. 308-313*).—The author finds that besides casein, albumin, and globulin, milk contains a fourth proteid, which he calls opalisin, on account of the opalescence of its solutions. The new proteid is obtained by precipitating the casein with acetic acid, and then saturating the curd with either magnesium sulphate, ammonium sulphate, or common salt. This precipitate differs from casein by not leaving any residue of pseudonuclein on digestion with pepsin. A neutral solution of the precipitate treated with a few drops of calcium chlorid and considerable phosphoric acid solution gives a precipitate of the opalisin.

It is present in considerable quantity in human milk, less in mares' milk, and in very small quantity in cows' milk. This constitutes another difference between human milk and cows' milk. The difficulty of precipitating the casein of human milk is said to be due to its opalisin. Mares' milk is in this respect, as in many others, intermediate between human milk and cows' milk.

The characteristics of opalisin are described.

On the yield and composition of sows' milk, W. A. HENRY and F. W. WOLL (*Wisconsin Sta. Rpt. 1897, pp. 10-19, fig. 1*).—Four farrowing sows were selected, 3 being pure-bred Poland Chinas and 1 a grade Chester White. Two of the sows were 2 years old and weighed nearly

450 lbs. each, while the other 2 were only 1 year old and weighed less than 300 lbs. each. The method of determining the yield was to weigh the pigs each time before and after suckling, keeping them confined between times in a pen near the dam. This weighing was continued on 3 days every 2 weeks until the pigs were weaned. In this way it was found that the average milk yield of the 4 sows ranged from 4.1 to 5.8 lbs. per day for the whole period of observation. The highest yield of milk in any one day was 8.7 lbs. and the lowest 1.2 lbs., the latter occurring just before weaning.

Some difficulty was had in securing samples of milk for analysis. "It was found that more milk could be obtained with less trouble by allowing a pig to empty an udder in part. At this stage the young animal was pushed aside, and the attendant quickly drew what milk he could from the teat before the dam became aware of what was happening." By this means small samples were obtained, seldom more than 1 fluid ounce. The analyses of 9 samples are tabulated. The average of these showed: Water 80.35 per cent, total solids 19.65, fat 8.24, and solids-not-fat 11.41. Excluding the first 2 analyses, which, owing to the smallness of the samples, were incomplete, the following averages are given for 7 samples:

Average composition of sows' milk, with variation.

	Average.	Lowest.	Highest.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Water.....	80.96	79.5	82.9
Fat.....	7.06	3.9	9.5
Casein and albumin.....	6.20	5.3	7.3
Milk sugar.....	4.75	3.1	6.0
Ash.....	1.07	.8	1.3
Solids-not-fat.....	11.99	10.8	13.2

These results are compared with those given for sows' milk by other writers and with the averages for cows' milk. The results of 68 analyses reported by Dietrich and König, Petersen and Oetken, and the authors show the fat in sows' milk to range from 1 to 16.1 per cent, the average being 6.74 per cent. The wide variations in the composition of sows' milk are explained by the fact that the samples obtained represent fractional milkings.

"The average daily yield of milk of the 4 sows ranged from 4.1 to 5.8, or about 5 lbs. a day. If we consider this yield an average for good sows, and the fat content above given, 6.74 per cent, an approximately correct figure, we have that a sow will yield 0.337 lb. of fat a day, a very fair performance for an animal weighing only one-third as much as an average cow, especially since the milk-producing faculties of the sow have hardly received any thought from the breeder or the feeder.

"The microscopic examination of the milk shows that the fat globules of sows' milk are of a very minute size, on the average only about one-quarter that of average-sized fat globules in cows' milk. On the other hand, the number of globules in a given volume of milk is about 8 times as large in sows' milk as in cows' milk."

Comparative investigations of the applicability of different tests for ascertaining the fat content of milk, F. FRIIS (*Ber. K. Vet. Landbohojskoler Lab., Copenhagen, 1898, pp. 112*).—The tests compared in this report are Gerber's acid butyrometer, Fjord's control centrifuge (cream test), and the "lactoscope." Earlier experiments at this station have demonstrated the accuracy of the Gerber test. The lactoscope is an apparatus invented by a Danish engineer, P. V. P. Berg, for determining the quality of milk. It is a Fjord centrifugal cream test, modified so as to be used with an Alpha separator. The apparatus consists of a hollow steel cylinder fitting into the Alpha separator stand. Loose aluminum plates shaped to hold 24 test tubes are placed in this cylinder, which will hold 16 plates, or 384 test tubes at a time. The milk in the tubes is heated to 40° C. and rotated for 35 minutes at a speed of 6,000 revolutions per minute. The results agree with those obtained with the Fjord cream test, each "per cent cream" being equivalent to about 1.5 per cent fat. The author concludes that the lactoscope when operated according to directions may be used with perfect assurance of accuracy in separator creameries and private dairies.—F. W. WOLL.

Rancid butter, A. J. SWAVING (*Ztschr. Untersuch. Nahr. u. Genussmitl., 1898, No. 11, pp. 759-762*).—The author reports two series of experiments with butter of unquestionable purity. In the first series, samples of melted and unmelted butter were kept in open and closed vessels, both in the dark and in the light, for 15 months, the volatile fatty acids being determined at the beginning and end of the experiment. There was a loss in volatile fatty acids in keeping the unmelted butter in both open and closed vessels, but a small increase in case of the melted butter.

The second series of experiments was like the first, except that the samples were kept for 5 years. The unmelted samples molded and assumed a dark color, while the melted samples remained a yellowish white and showed very little change in appearance. There was an increase in volatile fatty acids of the melted butter ranging from 1.7 to 2.3, the increase being greatest in the closed vessels. There was a loss of from 2.9 to 11.8 in case of the unmelted butter, the loss being materially greater in the open vessels, and in the dark.

The indications from these experiments are that in keeping unmelted butter there is a loss of volatile fatty acids, while in the case of melted butter the Reichert-Meissl number increases slightly. It is suggested that the difference in the behavior of melted and unmelted butter may be due to the presence of casein, milk sugar, and water in the unmelted butter. The greater loss of volatile fatty acids in darkness than in light is taken as a suggestion of the action of bacteria.

Experiments with a self-regulating pasteurizing apparatus, V. HENRIQUES and V. STRIBOLT (*Ber. K. Vet. Landbohojskoler Lab., Copenhagen, 1896, pp. 25; Tidsskr. Norske Landbr., 5 (1898), No. 10, pp. 527-533*).—The authors have adopted the principle of the Roux thermoregulator in constructing an apparatus which regulates the supply of milk to a

Fjord pasteurizer in such a manner that milk is admitted to the pasteurizer only when the temperature of the outgoing milk is above 85° C. If the temperature goes below 85° the difference in the expansion of the two parts of the regulator (a brass and a steel rod) closes a valve at the inlet and keeps it closed until the temperature of the milk at the outlet reaches 85°. The experiments made with the regulator in the laboratory and under factory conditions show that it will control the supply of milk so that the pasteurization temperature is practically constant at 85° C. The apparatus is described in detail in the report, and illustrations given of its various parts and connections.—F. W. WOLL.

Tolerance of certain milk bacteria toward ether. S. M. BABCOCK and H. L. RUSSELL (*Wisconsin Sta. Rpt. 1897, pp. 211-215*).—When fresh cheese curds were placed in an atmosphere saturated with ether vapor it was found that the oxygen disappeared entirely in a short time, being replaced by an equal volume of carbonic-acid gas. Microscopic examination showed that the whey expressed from these curds was teeming with bacteria. Cultures made from various colonies were placed in respiration chambers in atmospheres of ether, chloroform, and alcohol. There was evidence of growth except in the alcohol chamber.

Experiments to determine whether the organisms could live continuously were made with lactic-acid bacteria and with the organisms which have been found to grow in ether atmosphere. In these experiments the inspired air was drawn through ether, so that the air was saturated with ether vapor. The respiration of the lactic-acid cultures ceased within a short time after the admission of the ether, but that of the other culture continued for a period of 72 hours, the quantity of carbon dioxide evolved gradually decreasing during this period and finally ceasing.

“This experiment indicated that a saturated ether atmosphere was not especially suited for the development of the ether bacillus, but that it possessed a tolerance toward this anæsthetic that was far greater than any organisms heretofore reported.”

The ether organism was cultivated for a period of 8 months on artificial media, during which it seemed to lose its ether-tolerating property. The culture characteristics of the organism are described. “In milk cultures it produces an abundance of lactic acid from the sugar in the milk, thus causing it to curdle quickly. No gas is produced in the milk at all.”

Unorganized ferments of milk: A new factor in the ripening of cheese. S. M. BABCOCK and H. L. RUSSELL (*Wisconsin Sta. Rpt. 1897, pp. 161-193*).—The authors give a clear, concise account of the changes taking place in the ripening of cheese and the present status of the theories regarding the cause of these changes, followed by an account of their own investigations resulting in the discovery of an unorganized ferment as a natural component of milk.

“The enormous development of lactic-acid bacteria in hard cheeses and the elimination of the digesting or peptonizing organisms at an early stage of the ripening

has led Lloyd, working with English Cheddar, and Freudenreich, with the Swiss, both to ascribe to the milk-souring ferments the chief rôle in these changes.

"We have been able to confirm these results so far as the bacterial changes are concerned, but early in our work observations were made which did not conform to this theory.

"From two independent lines of research it became evident that profound changes of a physical and chemical nature occurred in milk in which bacterial fermentations had been excluded. In these experiments the casein of the milk underwent practically the same series of decomposition changes that are to be found in a ripening cheese, viz, the insoluble casein was converted into soluble proteids as indicated above.

"Parallel experiments with cheese gave the same result qualitatively and quantitatively; the products formed could not be distinguished from those of a normally cured cheese.

"Having eliminated the effect of the organized ferments (bacteria) by means of such chemical agents as ether, chloroform, benzol, etc., which do not affect the action of unorganized ferments, the conclusion was forced upon us that the changes which occurred were of a nonvital character and were undoubtedly due to enzymes. Two hypotheses as to the origin of these enzymes suggested themselves—either they were produced by bacteria which developed in the milk before the anaesthetics were applied, or they were inherent in the milk itself. The possibility of bacteria functioning in this way was excluded by securing milk drawn from the animal with great care and treated immediately with antiseptics. These freshly secured milks underwent identical changes with the others, showing that the enzymes were natural to the milk."

It was found that the proteids in separator slime digested more rapidly than those in skim milk, showing that the enzymes were separated in part in centrifugal creaming. Accordingly the slime was used for isolating the enzymes, the fresh slime being mixed with an equal weight of water containing 40 per cent of alcohol, the paste thus formed strained through cheese cloth, an antiseptic (either thymol or benzol) added to prevent fermentation, and the mass filtered after 24 hours. The filtrate was concentrated to about $\frac{1}{10}$ its volume (never heating over 25° C.). It was usually quite acid, and when neutralized with sodium carbonate gave a precipitate the filtrate from which was of a clear amber color, decomposed peroxid of hydrogen rapidly (a reaction common to most unorganized ferments), greatly hastened the formation of soluble products in milk, and liquefied gelatin.

"When added to milk it first coagulated the casein and afterwards redissolved the curd—the time required for this change depending upon the amount of extract added and the temperature. When the acid extract was added to milk the coagulation of the casein was hastened and the curd formed was firm and quite similar to that produced by rennet. In acid solution the digestion was much slower than in neutral or slightly alkaline solutions, indicating that the hydrolytic principle which it contains is more nearly related to a tryptic than to a peptic ferment. Attempts to obtain more concentrated extracts by precipitating the enzyme from the above extract with absolute alcohol have thus far failed."

Various experiments are reported showing how the formation of soluble proteids in milk is accelerated by the enzyme, that this power of digesting casein is destroyed by heat, and that the change does not occur as readily when even small amounts of hydrochloric acid are

present. "In this respect the character of the enzym present conforms closely to that of trypsin." Other experiments were made showing the power of the enzym extract to liquefy gelatin.

Tables are given showing the comparative rate of ripening in cheese and in milk. "The progressive nature of the changes in both cheese and milk are similar, the rate being somewhat more rapid in milk than in cheese, a fact of some moment when it is considered that bacterial activity was suspended in these milks."

The effect of temperature on ripening was also studied, cheese being kept at 55, 63, 73, and 86° F. The cheese kept at the higher temperatures ripened faster, which "is in conformity with what is well known concerning the action of enzymes under these conditions." A cheese more than a year old which has been kept under chloroform from the beginning, and, according to bacteriological examination, is perfectly sterile, is said to be thoroughly broken down, resembling a well-cured cheese. Chemical analysis shows that more than 50 per cent has been converted into soluble products. A sample of milk to which both ether and rennet were added after 4 months had 44.8 per cent of the total protein of the curd converted into soluble products. Both the cheese and the milk contained tyrosin and leucin like normal cured cheese. These same products were found in samples of skim milk kept under anaesthetic conditions for varying periods of time.

The authors discuss the relation of these inherent milk enzymes to current theories of cheese ripening and some other phenomena hitherto difficult to explain.

"It is our present belief that the ripening of hard cheese, instead of being due solely to bacteria, is caused by the joint action of both organized (bacteria) and unorganized ferments (enzymes). The breaking down of the casein is undoubtedly due, in larger part, to the action of enzymes. Concerning the production of the characteristic flavors, our knowledge is as yet too vague to warrant a definite assertion as to their origin. In all probability the bacteria in this relation play a much more important rôle."

Influence of temperature on the ripening of cheese, S. M. BABCOCK and H. L. RUSSELL (*Wisconsin Sta. Rpt. 1897, pp. 191-210, figs. 7*).—In the introduction the authors discuss the inadequate provision for curing cheese in the large majority of cheese factories, and call attention to the very deleterious effect of high temperatures on the quality of cheese. A diagram is given showing the actual temperature variation in an imperfectly constructed curing room in comparison with the variation in the cheese cellars of the Wisconsin dairy school. The zone which is stated to be invariably consistent with favorable results extends from 65° F. downward. In the investigations on the effect of temperature on the curing of cheese a special cheese-curing chamber was made in which the temperature could be controlled and varied at will by the use of ice or a gas burner, and another was made for lower temperatures (cold storage). The construction of these chambers is illustrated and described.

Five series of experiments were made, each series including from 3 to 5 full-sized cheeses made from mixed milk under identical conditions. These were cured at (1) a laboratory temperature, approximating 50° F.; (2) a normal curing-room temperature, ranging from 60 to 65°; and (3) an abnormally high temperature, 85°. Bacteriological and chemical examinations were made of the cheeses, the results of which are given:

“Results of bacteriological analyses.—(1) It was found that the bacterial flora of cheese cured at a low temperature (50 to 56° F.) retained for a certain period the same general aspect as that of the milk. In cheese cured under ordinary conditions there is almost immediately a differentiation as to the character of the micro-organisms present, the lactic-acid type acquiring the ascendancy. In the refrigerated cheese this change is much less marked in the beginning, although it does occur in the course of time.

“(2) Bacterial growth in the cold cheese develops more slowly than at higher temperatures and persists for a longer period of time.

“(3) In cheese cured at a higher temperature the number of bacteria per gram is greatly diminished when compared with either a refrigerator or normal temperature cheese, and the bacteria fail to persist for as long a period of time.

“(4) Not only is there a quantitative differentiation between cheese cured in low and high temperatures, but a qualitative change is also more or less marked. In the beginning of the ripening process the flora is practically the same, but in the cheese cured at high temperatures there is a strong tendency toward differentiation when compared with the flora of a refrigerator cheese. It is possible that this differentiation in species may stand in close relation to the varying flavors of cheese cured under these diverse conditions, and further experiments on this point are in progress.

“Results of chemical analyses.—(1) During the ordinary life of the cheese, the rate of curing changes is quite uniform, if the conditions are identical. When reduced to a curve it is apparent that it progresses somewhat more rapidly in the early stages than later.

“(2) The rate of the curing increases quite rapidly with a rise in temperature, and within the limits of our experiment has been nearly proportional to the temperature. Hence the cheeses cured at high temperatures were ready for consumption much earlier than those kept at low temperatures.”

It was found in these investigations that cheese ripened faster (as measured by the formation of soluble proteids) at a high than at a low temperature, whereas the cheese cured at a high temperature contained less bacteria than that kept in cold storage. In other words, where the curing was most rapid there was a diminished bacteria content, a relation which is thought to be contradictory to the theory that the ripening of cheese is due exclusively to the action of micro-organisms, but in harmony with the theory of the action of enzymes, “as the enzymes naturally inherent in the milk would act much more rapidly at higher temperatures than they would at a lower degree.”

The commercial value of the cold-storage cheese was rated by an expert at 7½ cts., that cured at normal temperatures at about the same price, while that cured at a high temperature “had a rank flavor and a value not exceeding 3 or 4 cts. a pound.” At that time prime Cheddar cheese was quoted at 7½ to 8 cts. The high temperatures impaired both the flavor and texture, whereas the cheeses cured at 55° and below were invariably of good quality and were entirely free from all bitter flavor.

The authors draw several practical deductions from the results of their work. "Here in Wisconsin the ordinary curing room almost invariably reaches a temperature in summer incompatible with proper curing," and as the expense of erecting suitable curing and storage rooms is considerable, central cooperative curing stations where the cheese from a number of factories could be shipped for ripening under safe and uniform conditions are suggested. The advantages of such a system are enumerated.

Further communications on the rôle of lactic-acid bacteria in the ripening of cheese, E. VON FREUDENREICH (*Milch Ztg.*, 27 (1898), No. 47, p. 738).—The author refers to his previous work on this question (E. S. R., 10, p. 687), and reports the results of examination of a number of milk cultures of different lactic-acid bacteria more than a year old. These are presented as additional proof of his theory that the formation of soluble proteids during ripening is principally due to lactic-acid bacteria. Mention is made of Campbell's work with pure cultures¹ and a footnote reference is given to Babcock and Russell's discovery of enzymes in milk (p. 785).

On the question of the decomposition of milk fat in the ripening of cheese, H. WEIGMANN and A. BACKE (*Landw. Vers. Stat.*, 51 (1898), No. 1, pp. 1-14; and in *Milch Ztg.*, 27 (1898), No. 48, pp. 757, 758; 49, pp. 771, 775).—Previous investigations by Weigmann and Henzold showed that in the ripening of cheese the greater portion of the fat was unchanged. According to earlier work by Weigmann the fat in the ripening of Emmenthaler cheese is either not altered at all or only very slightly. Duclaux, on the other hand, has found that fat undergoes a change during ripening, this change being only slight at first, but very considerable after a long time; and while the change is at first limited to the glycerid of the volatile fatty acids, it is later extended to the glycerid of oleic acid.

The authors used in their investigations a number of different kinds of cheese of different age, employing the following method of analysis: The cheese was rubbed with sand, extracted with ether, and the dried ether extract purified by taking up in petroleum ether, and again dried at 100 to 105° C. The free fatty acids in the petroleum ether solution were obtained by neutralizing this extract, dissolved in ether and alcohol, with decinormal soda solution. Any unchanged fat was removed by shaking with petroleum ether. The alcohol was evaporated from the soap and the residue treated with dilute sulphuric acid, and the melted fatty acids removed from the surface, washed with water, and used for further investigation.

The authors' investigations are believed to show that a decomposition of the fat takes place in the ripening of cheese, though much the larger part of the fat remains unchanged. The cheeses used, where of ordinary ripeness, contained from 1 to 7 per cent of the fat in the form of higher nonvolatile fatty acids. Of the hard cheeses, the newest

¹Jour. Highland and Agr. Soc. Scotland, 5. ser., 10 (1898), pp. 181-224; abstract will be given later.

(Edam, $2\frac{1}{2}$ months old) contained the smallest amount of fatty acids, while a soft cheese, only $\frac{1}{2}$ month older, contained nearly 7 per cent, indicating that the decomposition depends more on the intensity of the ripening of the cheese than on its age. The results also indicate that after a short time, even $2\frac{1}{2}$ months, the decomposition may extend to the glycerids of the nonvolatile fatty acids.

Statistical data relating to the cheese industry in Wisconsin, J. W. DECKER (*Wisconsin Sta. Rpt. 1897*, pp. 113-118).—Statistics are given for 104 factories, the data showing the daily milk supply, average fat content, number of patrons, number of cows supplying the milk, method of paying for the milk, distance which the milk is hauled, etc. Some difficulty was found in getting reliable data as to the number of cows milked by each patron, but the data for 66 factories out of the 104 show a total of 15,571 cows, or an average of 239 cows to a factory.

“These cows gave 271,078 lbs. of milk per day; that is, an average of 17.2 lbs. per cow. There were 1,617 patrons in these 66 factories, making an average of 9.1 cows per patron. The factories vary greatly in the average amount of milk per cow, viz, from 10 to 30 lbs. per day. In 11 factories the average daily milk yield per cow is 10 to 15 lbs.; in 29 factories, 15 to 20 lbs.; in 19 factories, 20 to 25 lbs.; and in 8 factories, 25 to 30 lbs.”

The other data are discussed at considerable length, and much interesting information is deduced as to the history of cheese factories, method of management, use of the Babcock test, payment of dividends, sale of cheese, character of buildings and equipment, curing rooms, disposition of the whey, prices of manufacture, etc.

Tables are given showing the temperatures recorded in different curing rooms, together with a description of the curing rooms at each of the 104 cheese factories. It was found that “the only curing rooms in the safe zone of temperature (see p. 787) were cellars and rooms ventilated by subearth ducts.” Where properly constructed subearth ducts are used “the owners claim better cheese and less drying out.” The method of building a duct is described. The system of central curing rooms for groups of factories is strongly recommended.

System of feeding milch cows at Ultana Agricultural Institute (Sweden) (*Nord. Mejeri Tidn.*, 13 (1898), No. 39, pp. 529, 530).

Feeding experiments with molasses and sugar-beet residue, A. OLSCHBAUR (*Deut. Landw. Presse*, 25 (1898), No 92, pp. 966, 967; 93, pp. 972, 973).—A practical experiment with 4 cows in which a mixture of molasses and the dried residue from sugar-beet factories was compared with the latter without molasses, the rest of the ration being uniform. The 2 rations were about equal in value for the production of milk and fat, but the manurial value of the molasses ration was somewhat greater, owing to the potash contained in the molasses.

Eleventh annual report of the dairy school at Rütli, Switzerland, 1897-98 (*Elfte Jahresbericht der Molkereischule Rütli pro 1897-98*. Bern: R. J. Wyss, 1898, pp. 54, pl. 1).—Aside from the report of the school work the results of some analytical and experimental work are given. A monthly record is given of the fat content of the milk furnished to the creamery by 31 patrons during the year. This ranged from 2.6 to 3.76 and averaged 4.9 per cent. Analyses are also given of the milk and products at each stage during the manufacture of butter and cheese, and also of butter from sweet and from ripened cream and whey butter. A feeding experiment

is very briefly reported, in which the addition of 1 kg. of sesame cake and 1 kg. of cracked wheat per day to the basal ration had a favorable effect on the fat production, the fat content diminishing when this was dropped and increasing when it was restored in a subsequent period. In another experiment an increase in the amount of grain to 4 kg. is stated to have resulted in a decrease in the fat content of the milk.

The employment of artificial rennet preparations in cheese making, E. von Freudenreich and R. Steinegger (pp. 52-54).—Two experiments were made in the use of artificial rennet, against which there is said to be more or less prejudice in Switzerland. The conclusion is that artificial rennet, when properly prepared, is quite as well adapted to cheese making as natural rennet, and possesses some advantages, such as uniformity and convenience in using.

Composition of Swedish milk for infants, 1896-97 (*Nord. Mejeri Tidn.*, 13 (1898), No. 37, pp. 509, 501).—Monthly averages for the contents of solids and fat and the specific gravity of certified milk for infant feeding supplied by the Stockholm Milk Commission. The average data for the whole year were as follows: 1896, specific gravity 1.0328, solids 12.03 per cent, and fat 4 per cent; 1897, specific gravity 1.032, solids 12.68 per cent, and fat 3.97 per cent. Average analyses of ordinary Stockholm whole milk are given by months, the mean fat content for the years 1896 and 1897 being 3.65 and 3.68 per cent, respectively.—F. W. WOLL.

State standards for dairy products, H. E. ALVORD (*U. S. Dept., Agr., Bureau of Animal Industry Circ.* 25, p. 1).—The standards for milk, skim milk, cream, butter, and cheese compiled from State dairy laws.

Report of milk-control stations of Norway, 1897 (*Aarsber. Offent. Foranst. Fremme, 1897*, pp. 205-210).—Three of the stations were in operation during 1897, viz. in Christiania, Bergen, and Trondhjem. The total number of samples of whole milk tested for fat content was: Christiania 32,259, Bergen 15,495, and Trondhjem 30,927 samples. The fluctuation in the monthly averages (which are in each case made up of a fairly uniform number of samples) and the annual averages for the 3 stations are shown below:

Average percentage of fat found in whole milk, 1897.

Month.	Milk-control station at—			Month.	Milk-control station at—		
	Christi- ania.	Bergen.	Trond- hjem.		Christi- ania.	Bergen.	Trond- hjem.
January	3.39	3.35	August	3.46	3.90	3.49

—F. W. WOLL.

Methods of adulteration of butter and cheese, J. LANDIN (*Nord. Mejeri Tidn.*, 13 (1898), No. 39, p. 527).

Dairy legislation, J. W. ROBERTSON (*Rpt. Comr. Agr. and Dairying Canada, 1897*, pt. 10, pp. 5-16).—Enactments affecting the dairy interests in Canada are quoted and discussed in a popular manner.

The milk supply of Padua (Italy), E. CAPPELLETTI (*Sul. letta die Padova. Ricerche chimico-Batteriologiche. Institute of Hygiene of the Univ. of Padua, 1897*, pp. 40).—A chemical and bacteriological study.

Centrifugal milk analysis, F. W. WOLL (*Jour. Appl. Micros.*, 1 (1898), No. 12, pp. 209-211, fig. 1).—An adaptation of a urinary centrifuge to the testing of milk by the Babcock method. Although only about one-ninth as much milk is taken as in the regular Babcock test, there is said to be no difficulty in obtaining accurate results after a little practice.

Dairy bacteriology, W. T. CONNEELL (*Rpt. Comr. Agr. and Dairying Canada, 1897*, pt. 16, pp. 4-16, figs. 13).—This treats in a popular manner of the characteristics of bacteria, fermentations of milk, pasteurization, means of infection, fermentation in cheese making, etc.

Sterilizing milk: Improved method of and apparatus for, N. BENDIXEN (*English Pat. No. 12869; Jour. Soc. Chem. Ind., 17 (1898), No. 11, p. 1067*).—The method employed is to saturate the milk with carbon dioxide, boil for about half an hour under pressure at a temperature of about 120° C., and then to pass a current of pure sterile air through it. The milk is said to retain its taste and other properties. The apparatus used is described in the abstract.

Pasteurization and pure culture in Swedish creameries, N. ENGSTRÖM (*Tidskr. Landtman, 19 (1898), No. 38, pp. 675-680; Nord. Mejeri Tidn., 13 (1898), No. 40, pp. 543-545*).—During 1897, 317 creameries or private dairies participated in the Swedish butter exhibitions. Of these, 66.9 per cent pasteurized their cream all the time, 16.1 per cent did so at times, and 16.4 per cent not at all; 19.9 per cent used pure-culture starters regularly, 16.1 per cent at times, and 57.1 per cent not at all; 3.5 per cent churned sweet cream, and 2.5 per cent were radiator creameries. The proportion of creameries which pasteurize their cream and use pure cultures has steadily increased of late years.

Of the pasteurized butter exhibited, 51.7 per cent, on the average, was scored in class 1 (fine), 35.4 per cent in class 2 (good), and 12.9 per cent in class 3 (fair). Of the unpasteurized butter 16.3 per cent was scored as fine, 42.9 per cent as good, and 40.8 per cent as fair.—F. W. WOLL.

On the making of butter, J. W. ROBERTSON (*Rpt. Comr. Agr. and Dairying Canada, 1897, pt. 4, pp. 17-23*).—Popular notes on the separating, ripening, and churning of cream, and the working, packing, and handling of butter.

The development and present status of cooperative creameries in the Grand Duchy of Mecklenburg-Schwerin, J. SIEDEL (*Milch Ztg., 27 (1898), No. 48, pp. 753-755; 49, pp. 770-772; 50, pp. 788, 789; 52, pp. 819-821*).

Statistics from fifty-two Wisconsin separator creameries, E. H. FARRINGTON (*Wisconsin Sta. Rpt., 1897, pp. 82-112*).—A reprint, somewhat abridged, of Bulletin 56 of the station (E. S. R., 9, p. 286).

The distribution of cheese and butter factories in Wisconsin, S. M. BABCOCK, H. L. RUSSELL, and J. W. DECKER (*Wisconsin Sta. Rpt., 1897, pp. 149-152, pt. 1*).—According to this article there were in Wisconsin, in 1897, 951 creameries and 1,571 cheese factories. An account is given of the development and growth of the dairy industry in the State and the present distribution of butter and cheese factories, and a plate showing their location.

“Since 1890 the cheese industry has remained practically at a standstill, although the butter production has largely increased. The reason for this is the relatively higher price for butter during this period, a condition that was caused to a considerable extent by the manufacture of fraudulent cheese products (skimmed and filled cheese).”

Preparation of cheeses from sheep's milk (*Poliara, 1897, pp. 12; rev. in Selsk. Khoz. i Lyesor., 188 (1898), No. 2, p. 474*).—This includes a description of the making of “Pekarino” cheese by E. E. Rostovtsev and of “Crinza” and “Kaehkaval” cheeses by S. G. Leontovich.

The biology of cheese ripening, S. M. BABCOCK and H. L. RUSSELL (*Proc. Amer. Assoc. Adv. Sci., 47 (1898), pp. 420, 421*).—The authors report the discovery in milk of an unorganized ferment, “galactase” (E. S. R., 9, p. 205), and discuss the importance of its bearing on the ripening of cheese.

The occurrence of relatively large colonies of bacteria in inferior Emmenthaier cheese, R. BURRI (*Centbl. Bakt. u. Par., 2. Abt., 4 (1898), No. 15-16, pp. 608-615*).—A cheese was examined which contained numerous dark-colored spots, occurring all through the cheese. Investigation showed the spots to be due to large colonies of bacteria, and that all the colonies were of one and the same species of bacteria.

The micro-organism was isolated and studied. It is suggested that possibly the conditions at the points where the spots occurred were so especially favorable for the bacteria that they were able to withstand the competition of other bacteria and formed relatively large colonies, visible to the naked eye.

On the formation of holes in cheese, F. BAGGE (*Nord. Mejeri Tidn.*, 13 (1898), No. 35, pp. 475-477).

VETERINARY SCIENCE AND PRACTICE.

Proceedings of the second annual meeting of the Association of Experiment Station Veterinarians (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 22, pp. 29*).—In addition to the usual statistical information the report contains the papers presented at the meeting of the Association at Omaha, September, 1898. These were: Growing tubercle bacilli for tuberculin, C. A. Cary; The experiment station veterinarian as a member of the State Board of Health; Laboratory records for veterinarians, A. W. Bitting; The desirability of cooperation between the station veterinarian and local veterinarians in the State, A. W. Bitting; The exhibit of the United States Experiment Station veterinarians at the Paris Exposition in 1900, A. T. Peters; The value to veterinarians of cooperative experiments, L. L. Lewis; Constitution and by-laws of the Association of Experiment Station Veterinarians, and Feeding wild plants to sheep, S. B. Nelson.

The last article reports the feeding of a number of plants, several of which are regarded as poisonous, to sheep. These were: *Delphinium menziesii*, *Castilleja pallescens*, *Crepis barbigera*, *Astragalus dorycnoides*, *A. spaldingii*, *A. palousensis*, *Zygadenus venenosus*, *Frasera albicaulis*, *Antennaria luzuloides*, *Sisyrinchium grandiflorum*, and *Arnica fulgens*.

The following plants, which are not regarded as poisonous, were also fed: *Saxifraga integrefolia*, *Lupinus ornatus*, *Leptocnium multifida*, *Peucedanum grayii*, *Synthyris rubra*, *Clematis douglasii*, *Heuchera glabella*, *Lithospermum pilosum*, Geranium, *Potentilla*, *Eriogonum heracleoides*, *Geum triflorum*, *Grindelia nana*, and *Chaenactis douglasii*.

Negative results were obtained in all cases.

Sheep scab: Its nature and treatment, D. E. SALMON and C. W. STILES (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 21, pp. 61, pls. 6, figs. 35*).—This is an extended discussion of the subject. In addition to historical matter, the principal points treated of are the cause of the scab, description of the scab of different sorts and treatment, and the conditions which may be mistaken for scab. Dipping is regarded as the most effective treatment for scab, and detailed descriptions are given of different methods of conducting this operation. Federal laws and regulations relative to sheep scab are quoted.

On bovine tuberculosis and its eradication, O. MALM (*Tidsskr. Norske Landbr.*, 5 (1898), No. 10, pp. 475-535).—This is a general discussion of the subject, with special reference to conditions in Norway. From 1895 to 1897, inclusive, 55,542 animals have been tested with tuberculin under the author's direction. Of these, 36 per cent were found to be affected with tuberculosis. The animals examined

were distributed in 1,331 herds, 26.55 per cent of this number containing tuberculous animals. According to an earlier investigation¹ of the author's, different breeds of cattle have shown the following percentages of tuberculous individuals: Common Norwegian natives, 6.7 per cent; Telemark, 4.9 per cent; Ayrshire, 15.1 per cent; mixed breeds, 12.4 per cent; various or unknown breeds, 3.8 per cent. According to the age of the animals, reaction to the tuberculin test was as follows: Under 6 months, 1.9 per cent; 6 months to 1 year, 3.2 per cent; 1 to 5 years, 7.1 per cent; over 5 years, 10.4 per cent; age not known, 7.5 per cent.—F. W. WOLL.

Milk from tuberculous cows, C. H. HARRISON (*Ontario Agr. Col. Rpt. 1897*, pp. 147-149).—Experimental tests showed that milk may be tuberculous though the udder is not affected. In one case a cow gave no reaction, but was found upon *post-mortem* examination to be generally affected with tuberculosis. One of the cows gave a reaction, but the milk was not affected.

On the chemistry of tubercle bacilli, W. G. RUPPEL (*Ztschr. Physiol. Chem.*, 26 (1898), No. 3-4, pp. 218-232).

Tuberculin, C. H. HARRISON (*Ontario Agr. Col. Rpt. 1897*, pp. 144-147, figs. 4).—Popular directions for applying the tuberculin test are given, together with a summary of tests made with the herd at the college farm. One hundred and sixty, or 24 per cent of the 762 animals tested, were diseased.

Report of superintendent of the civil veterinary department, F. RAYMOND (*Ann. Rpt. Civ. Vet. Dept. [Bengal]. 1897-98*, pp. 29).—In addition to statistical and other information concerning the Bengal Veterinary Institution, the article contains an account of rinderpest experiments and information concerning contagious diseases in various districts of India.

Blackleg, E. P. NILES (*Virginia Sta. Bul. 75*, pp. 37-42).—This is a general article describing the causes, symptoms, and treatment of blackleg. The fact is emphasized that the only hope of exterminating this disease lies in combative treatment by vaccination.

The cattle tick in Virginia, E. P. NILES (*Virginia Sta. Bul. 76*, pp. 47-50).—The author describes the different cattle ticks. The regions in Virginia already infested with them are mentioned and the desirability of quarantine is pointed out. The various methods of preventing ticks are described and measures discussed for exterminating them in Virginia and preventing their importation.

Modern views as to milk fever and its treatment, A. BERGSTRAND (*Laudmansblad*, 31 (1898), No. 19, pp. 147-148).

Concerning the bacteria in the air passages, T. BARTHEL (*Centbl. Bakt. u. Par.*, 1, *Abl.*, 24 (1898), No. 11, pp. 401-414; 12, pp. 433-441).—The bacteria of the trachea, bronchial tubes, etc., were examined.

An active principle in millet hay, E. F. LADD (*Amer. Chem. Jour.*, 29 (1898), No. 10, pp. 862-866).—The author reports the isolation of a glucosid from the aqueous extract of millet hay, which on small animals produced the characteristic symptoms of millet disease.

Poisoning of cattle by the saltpeter on the walls of stables, L. GRANDEAU (*Jour. Agr. Prat.*, 1898, II, No. 50, pp. 846, 847).

Poisoning of swine by too heavy molasses feeding, L. BRANTE (*Tidskr. Lantmån*, 19 (1898), No. 42, pp. 758-760).—Three fattening pigs, 7 to 9 months old, fed for 3 weeks on molasses feed (1 part bran, 1 part palm-nut meal, and 2 parts molasses), were taken suddenly sick, and were killed in a dying condition. The presence of potash salts in the molasses is ascribed as the cause.

Cribbing and its operative treatment, S. J. J. HARGER (*Jour. Comp. Med.*, 20 (1899), No. 1, pp. 22-25).—A number of cases are briefly reported.

A new method of employing charcoal in the treatment of acute indigestion in horses, G. J. GOUBEAUD (*Jour. Comp. Med.*, 20 (1899), No. 1, pp. 16-22).—A paper read before the Veterinary Medical Association of New York County, New York.

¹ Report Veterinary Department for 1896, Norges Offic. Statistik., 3. ser., No. 299.

The author recommends that charcoal should be heated before administration to drive off the absorbed gases.

The disappearance of pathogenic organisms from manure and compost, A. GÄRTNER (*Ztschr. Hyg. u. Infektionskrankh.*, 28 (1898), No. 1, pp. 1-15).

Notes on an experimental study of the disinfecting power of common soap, J. ALEXANDROW (*Russk. Arch. Patol. Klin. Med. i Bakt.*, 1 (1897), No. 6, pp. 676-685).

Experimental studies on the disinfecting power of ordinary soaps, A. SERAFINI (*Arch. Hyg.*, 33 (1898), No. 4, pp. 369-399).—A number of experiments are reported.

The investigation of Dr. Koch on animal diseases in Africa, E. L. (*Rec. Gén. Agron.*, 7 (1898), No. 11, pp. 487-491).—A brief summary.

The literature of veterinary medicine and allied sciences, R. SCHÖTZ (*Die Literatur der Veterinärwissenschaft und verwandter Gebiete. Berlin, 1898: rec. in Ztschr. Fleisch u. Milchhyg.*, 9 (1898), No. 2, p. 37).—The period covered is from April 1, 1889, to July 1, 1898.

AGRICULTURAL ENGINEERING.

Loss from canals from filtration or seepage, L. G. CARPENTER (*Colorado Sta. Bul.* 48, pp. 36, fig. 1).—A series of observations were made on "stretches of canals in the Platte Valley and Cache la Poudre Valley near Fort Collins and several in the San Luis Valley, and one canal on which automatic records were kept for 2 years. The method of measurement was essentially the same in all cases, namely, to measure the amount flowing in the canal at different points, and then to compare the increase or decrease in the amount of water in the canal after allowing for the water taken out by laterals between the points of measurement."

The results are discussed in detail and summarized as follows:

"(1) The losses from evaporation are relatively insignificant compared with the seepage losses from most canals. In the cases most favorable to evaporation and least favorable to seepage the evaporation is not over 15 per cent of the seepage.

"(2) In the case of reservoirs it was concluded in bulletin 45 that the seepage was less important than the evaporation. This is different from the results found in ditches, not because the evaporation is less, but because the seepage is much more.

"(3) The losses are sometimes enough to cover the whole canal 20 ft. deep per day.

"(4) The loss in clay soils is less than in sandy or gravelly soils, but rarely as small as 3 in. daily.

"(5) The loss is greater when water is first turned in than after the bed has become saturated.

"(6) Sometimes the canals are found to gain for the whole or part of their length or the canals may act as drains. This is more likely to be the case when the canal is deep in the ground, when crossing lines of drainage, or when located below other ditches or irrigated tracts.

"(7) In the prevailing Colorado soil, when not intercepting seepage, the loss may be put provisionally at from 1 to 2 ft. per day over the whole surface of the canal. In clay soils it is less, but still nearly one-half as much.

"(8) The loss in carrying water in small quantities is relatively larger than in carrying large amounts. The increased depth of water means increased leakage, but the carrying capacity increases faster than the leakage.

"(8a) From the standpoint of economy it is wasteful to run a small head. It is more economical to run a large head for a short time. In the management of small ditches the time system of distribution can be introduced to advantage, saving time and labor as well as water.

"(9) It is wasteful to use 2 ditches or laterals when 1 would serve.

"(10) The loss increases with higher temperature, being about twice as much at 80 as at 32.

"(11) The loss increases with greater depth of water, but the exact relation needs further investigation.

"(12) The loss will be lessened by any process which forms or tends to form an impervious lining or coating of fine material, as of clay or silt. The silt, consisting of fine sand, improves many soils. Clay is better and especially limy clay, the lime with the clay forming an almost impervious coating.

"(13) Cement linings as used in California and Mexico are not warranted by the conditions in Colorado, nor would the weather conditions be favorable. Nor is the use of wooden stave piping for this purpose likely to be profitable in many places in the State, if at all on the larger canals at present. The silting process applied with discrimination will accomplish much at smaller cost.

"(14) On small laterals glazed sewer pipes may save annoyance often connected with the carrying of water in laterals for considerable distances, which, with the saving of water, may make its use an object. One of the supply laterals of the Colorado Agricultural College is of vitrified sewer pipe, over 4,000 ft. of 12-inch pipe being used.

"(15) Some particular sections in canals are subject to much greater loss than the canal as a whole. Hence water can be saved by locating the leaky place and remedying it. This may be desirable to do while it would be unprofitable to treat the whole canal.

"(16) There are many places where it would be advantageous to combine 2 ditches, by this means saving not only the loss of water, but saving superintendence and maintenance charges. With increased confidence in the accuracy of water measurement, reluctance to such consolidations should lessen.

"(17) The depth of losses from laterals is probably greater than in the main ditches. The laterals are less permanent, are steeper, have less silt, and are more poorly cared for.

"(18) There must be some arrangement of ditches and laterals which is the most economical for given conditions, so that the aggregate of the losses of the whole system will be a minimum. Certainly the location and arrangement of the laterals for carrying water from the main ditch is worthy of consideration by the management of the main canal, and the importance increases with the size of the canal and the width of the strip it serves.

"(19) It is not to be understood that the whole of the loss from the ditches is lost to the public wealth of the State. Some, perhaps much, of the loss, may reappear as seepage in lower ditches or in the main stream and again be used. It is, however, lost to the particular ditch, and incidentally is destructive to much land. With all practicable methods of prevention there will still be abundant loss. It should be to the advantage of the individual ditch to prevent such loss as far as practicable.

"(20) A general statement of the total amount of loss of water must be made and accepted with reservation. It would appear that in the main canals from 15 to 40 per cent is lost, and in the laterals as much more. It would thus appear that not much over one-half, certainly not over two-thirds, of the water taken from the stream reaches the fields. In the most favorable aspect the loss is great, and is relatively greatest when the loss can be least afforded, viz, when the water is low and the ditches are running with reduced heads.

"(21) There are some 2,000,000 acres of land irrigated in Colorado, and the value of the water rights at a low estimate is as much as \$30,000,000. (The census estimates the water rights as worth \$28.46 per acre.) On this basis the capital value of the water lost by seepage in the canals and ditches may be put at from \$6,000,000 to \$10,000,000. From the evidence at hand at present this seems a low estimate."

Report of trials with insulating materials, E. J. BONNESEN (*Tidsskr. Landökon.*, 17 (1898), No. 5-6, pp. 379-394).—The materials tested were placed between zinc cylinders 19 in. in diameter and 3½ ft.

high, and galvanized-iron cylinders 25 in. in diameter and 4 ft. high (placed one within the other). Ice was kept in the zinc cylinders, and the water melted from the ice weighed twice a day, the room temperature being kept constant throughout the trial, which lasted about 3 weeks. The following table gives a summary of the observations taken:

Trials with insulating materials, 1898.

	Weight of melted ice in 24 hours.	Weight of insulating material.	Comparative insulating power.	
			Thick-ness.	Weight.
	<i>Pounds</i>	<i>Pounds.</i>		
Cork refuse.....	5.97	47.0	78.2	61.8
"Cork stone," crushed.....	6.84	81.5	89.6	122.7

—F. W. WOLL.

A simple and efficient method of irrigating the soil, C. SCHULER (*Landw. Jahrb. Schweiz, 11 (1897), pp. 369-377, pls. 2, chart 1*).—The distribution of rainfall (with chart of normals) and the need of irrigation in Switzerland are discussed, the conclusion being reached that only simple, cheap methods of irrigation can be profitably employed. A method of irrigation in which the soil is flooded by means of gates at intervals in the ditch is described.

Manure platforms, M. RINGELMANN (*Jour. Agr. Prat., 1898, II, No. 51, pp. 892-897, figs. 7*).—Plans and descriptions are given,

Manure yards, M. RINGELMANN (*Jour. Agr. Prat., 1898, II, No. 52, pp. 923-926, figs. 4*).—Plans and descriptions of covered and uncovered yards.

Pit or platform for manure, H. D'ANCHALD (*Jour. Agr. Prat., 1899, I, No. 3, pp. 93, 94*).—A brief note on the relative merits of these two means of storing manure.

The amount of water pumped by a geared 16-foot aermotor windmill, F. H. KING (*Wisconsin Sta. Rpt. 1897, pp. 240-248, figs. 3*).—This is a preliminary account of experiments more fully reported in Bulletin No. 68 of the station (E. S. R., 10, p. 695).

The Venturi meter (*Jour. Franklin Inst., 147 (1899), No. 2, pp. 108-115, figs. 23*).—Report of the Committee on Science and the Arts of the Franklin Institute on the inventions of Clemens Herschel, Frederick N. Connet, and Walter W. Jackson. The Elliott-Cresson Gold Medal (the highest honor in the gift of the institute) was awarded to the first mentioned for the invention of the Venturi tube, and the John Scott Legacy Premium to the other two for their registering apparatus adapted to use with the Venturi meter.

Lightning rods and protection of farm buildings from lightning, R. C. KEDZIE (*Michigan Sta. Spec. Bul. 3, pp. 8*).—A popular article.

STATISTICS—MISCELLANEOUS.

Report of Idaho Station for 1898 (*Idaho Sta. Bul. 15, pp. 139-180*).—This contains reports of the director and the heads of departments, parts of which are noted elsewhere, on the station work for the year, and financial statements for the fiscal years ending June 30, 1897 and 1898.

Annual Report of South Dakota Station, 1898 (*South Dakota Sta. Rpt. 1898, pp. 7-19*).—This contains a report of the director, including a financial statement for the

year ending June 30, 1898, and brief reports of the agriculturist, horticulturist, chemist, and botanist and entomologist.

Sixth Annual Report of Washington Station, 1896 (*Washington Sta. Rpt.*, 1896, pp. 56).—This includes reports by the director, botanist and entomologist, veterinarian, horticulturist, and chemist; a meteorological report, and a financial report for the fiscal year ending June 30, 1896. Some of these are noted elsewhere.

Fourteenth Annual Report of Wisconsin Station, 1897 (*Wisconsin Sta. Rpt.*, 1897, pp. 338).—This contains the report of the director on the station staff, work, and publications; various articles noted elsewhere; lists of exchanges and acknowledgments; and a financial statement for the fiscal year ending June 30, 1897.

Report of the agricultural department, Finland, for 1896, N. GROTFELT (*Landbr. Styr. Meddel.*, 1896, No. 24, pp. 207).

Report of the agricultural department, Norway, for 1897 (*Aarsber. Offent. Foranst. Fremme*, 1898, pp. 478).

Report of the agricultural experiment station of Poltava for 1896, V. N. DIAKOV (*Poltava*, 1897, pp. IV+207; rev. in *Selsk. Khoz. i Lysov.*, 188 (1898), No. 2, pp. 470, 471).

Constitution of the Association of Agricultural Experiment Stations in the German Empire (*Landw. Vers. Stat.*, 51 (1898), No. 1, pp. 83-86).—Text of the constitution as it now stands.

NOTES.

ALABAMA CANEBRAKE STATION.—W. M. Booker, a member of the governing board, has recently died. The vacancy in the board has not yet been filled. The Thirteenth Annual Report of the station has just been issued.

IOWA STATION.—Arrangements have been made for a series of experiments in roadmaking at the station during the coming season, in cooperation with the Office of Road Inquiry of this Department.

KANSAS COLLEGE AND STATION.—A. J. Burkholder, M. D., D. V. S., has been appointed assistant in veterinary science and biology in the college and station. The number of farmers' institutes held this year has been greater than ever before, being 62. This result has been attained by grouping institutes so that several could be attended at one trip, thus saving both time and expense. Three sets of bulletins are sent out: The ordinary pamphlet bulletins, weekly press bulletins to the county newspapers, and another set of occasional press bulletins in mimeograph typewriting to the agricultural papers which circulate in Kansas. During February and March an extra number of some of the press bulletins is printed and mailed to the pamphlet bulletin list; at the same time an unusual number of different press bulletins is issued, the object being to place before the farmers information which they need at this season. The State legislature has appropriated \$25,000 for a dairy building, \$6,000 for equipment, and \$3,000 for a herd and stable.

MICHIGAN COLLEGE AND STATION.—The following changes have been made in the governing board of the station: E. P. Allen, of Ypsilanti; H. F. Marsh, of Allegan, and L. Whitney Watkins, of Manchester, have been appointed, *vice* Arthur C. Bird, Charles W. Garfield, and Charles F. Moore, retired. T. F. Marston, of Bay City, has been elected president of the board, *vice* Franklin Wells, who still continues on the board. Arthur C. Bird has succeeded Ira H. Butterfield as secretary of the State board of agriculture and secretary and treasurer of the station. The work of the farm department has been subdivided, the field crops and plat work being placed in charge of J. D. Towar, the live stock under H. W. Mumford, and the dairy work under G. H. True. During the season of 1899 the work with sugar beets will be continued, sending out seed furnished by the Government for definite experiments as to fertilizers and methods of cultivation. At the station the plat work with sugar beets will relate to kinds and methods of application of fertilizers and means of avoiding as far as possible the work of thinning. Experiments are being concluded on the feeding of beet pulp to dairy cows.

NORTH CAROLINA COLLEGE AND STATION.—The new members of the board of trustees, elected by the General Assembly March 6, are as follows: Frank Wood, of Edenton; J. B. Stokes, of Windsor; W. J. Peele, of Raleigh; D. A. Tompkins, of Charlotte; E. Y. Webb, of Shelby; W. C. Fields, of Sparta; J. Frank Ray, of Franklin; W. H. Ragan, of High Point; David Clark, of Charlotte; T. B. Twitty, of Rutherfordton; A. Leazar, of Mooresville; H. E. Bonitz, of Wilmington; R. L. Smith, of Albemarle; H. E. Fries, of Salem; and P. J. Sinclair, of Marion. W. S. Primrose, of Raleigh, has been elected president of the board, *vice* J. C. L. Harris, resigned. Mr. Harris is still a member of the board. The terms of office of the following have expired: J. J. Britt, J. R. Chamberlain, S. L. Crowder, and W. C. O'Berry. Cooper Curtice, veterinarian, has been granted leave of absence for the

remainder of the fiscal year, to enter the service of the State Department of Agriculture. In accordance with the act of the General Assembly of 1899, on July 1 next the analytical work of the fertilizer control will be performed by the chemist of the State Department of Agriculture and not in connection with the station. On July 1, therefore, the fertilizer control division of the station will be discontinued.

OKLAHOMA COLLEGE AND STATION.—The following appointments have been made on the board of regents: Jas. P. Gandy, of Alva, *vice* B. S. Barnes, late president of the board, and J. D. Ballard, of Weatherford, *vice* R. J. Edwards. F. J. Wykoff, of Stillwater, has been elected president, and C. J. Benson, of Shawnee, has been reelected treasurer of the board. The State legislature has made appropriations approximating \$30,000 for buildings and equipment and about \$8,000 for maintenance of the college for the next two years. It is expected that these sums will be appropriated in such ways as to considerably increase the facilities for work by the station staff.

TEXAS COLLEGE AND STATION.—A bill has recently passed the State legislature providing for a State entomologist to study the cotton bollworm and other insect pests of the State and to give instruction in entomology at the college. An appropriation of \$5,000 is made for salaries and other expenses.

VERMONT STATION.—W. C. Norcross has been succeeded by G. W. Strong as dairyman.

WEST VIRGINIA UNIVERSITY AND STATION.—The Mechanical Hall of the university was destroyed by fire March 4, together with the valuable equipment which it contained. The building and contents were valued at \$40,000. The insurance carried on the building was \$28,000. The net loss will not exceed \$1,600. Arrangements for rebuilding are being made. The State legislature has appropriated \$5,500 for the station, to defray the expense of printing bulletins and reports, purchasing stationery, and office supplies, etc.

WYOMING UNIVERSITY AND STATION.—The station farm has been increased by the addition of 80 acres of land under the Pioneer Canal, along with the water right for the same. This land is to be held as the property of the university so long as it is used for experimental purposes. The land is virgin soil, having never been fenced or plowed. It joins the present farm on the south and will be used mainly for some extensive field experiments in irrigation.

ASSOCIATION OF OFFICIAL AGRICULTURAL CHEMISTS.—F. S. Shiver, Clemson College, South Carolina, is the referee for nitrogen for the coming year, instead of B. L. Hartwell as stated in a former issue (E. S. R., 10, p. 512).

NECROLOGY.—Dr. Albert Schultz died at Lupitz, Germany, January 5, 1899, at the age of 68 years. He was one of the most prominent agriculturists of Germany, and widely known as the originator of the Schultz-Lupitz system of culture, by which poor, sandy soils are brought to a state of fertility through the combined use of leguminous crops in the rotation and phosphates and potash salts as fertilizers. Schultz-Lupitz was a charter member of the Deutsche Landwirtschaftliche Gesellschaft, and a prolific writer on agricultural subjects. For several years he was a member of the German Reichstag. The utility of his system of culture, especially the importance of legumes in the rotation for the assimilation of the free nitrogen of the air, was demonstrated under his management on his own lands. His estate was formerly known as the Desert of Lupitz, the soil being a coarse-grained, diluvial sand, destitute of lime and extremely poor in potash, nitrogen, and phosphoric acid. Through his method of culture the estate was brought to its present high state of fertility.

EXPERIMENT STATION RECORD.

VOL. X.

No. 9.

The act of Congress making appropriation for this Department for another year includes several new features which, together with increased funds for many of the bureaus and divisions, will materially strengthen the Department and extend its sphere of usefulness. It provides an increase of nearly \$200,000 over last year and of more than half a million dollars over the year previous, the total appropriation for the closing fiscal year of the century being \$3,726,022. This includes the \$720,000 for the agricultural experiment stations in forty-eight States and Territories, and a special appropriation for the establishment and maintenance of experiment stations in Alaska.

The largest increases in appropriation are for the Weather Bureau and the Bureau of Animal Industry. The total appropriation for the Weather Bureau is \$1,022,482, which includes an increase of \$60,000 for the maintenance of the new stations in the West Indies and adjacent coast, and \$25,000 for the erection of an addition to the present buildings of the Bureau in Washington.

The total appropriation for the Bureau of Animal Industry is \$1,044,030. This includes \$50,000 additional for investigations and inspection and \$20,000 "for the purchase and equipment of land in the vicinity of Washington for an experiment station for the study of the diseases affecting the domesticated animals." The Secretary of Agriculture is also authorized to expend a sum within his discretion "for promoting the extension and development of foreign markets for dairy and other farm products of the United States."

The fund for irrigation investigations has been increased to \$35,000, \$10,000 of which is made immediately available. The object stated is "to investigate and report upon the laws and institutions relating to irrigation and upon the use of irrigation waters, with special suggestions of better methods for the utilization of irrigation waters in agriculture;" and it is directed that this investigation shall be carried on in cooperation with the experiment stations, "in such manner and to such extent as may be warranted by a due regard to the varying conditions and needs of the respective States and Territories and as may be mutually agreed upon."

The scope of the Division of Forestry is enlarged to include the subjects of forest fires, lumbering, the advising of owners of woodlands as

to their proper care, and forestry experiments for the treeless region. An increase of \$20,000 is provided, making a total of \$48,520 for this division.

An appropriation of \$10,000 is made for tobacco investigations, including the mapping of tobacco soils; study of soils and conditions of growth in Cuba, Sumatra, and other competing countries; investigations on the methods of curing, with particular reference to fermentation; and originating improved varieties by means of selection and breeding. These investigations will be in charge of the Division of Soils.

The Division of Chemistry receives \$34,000—an increase of \$5,300—\$2,500 of which is for the equipment of the new laboratory and is made immediately available. A new clause relative to investigation on the adulteration of foods, drugs, and liquors authorizes the Secretary of Agriculture to procure through the Secretary of the Treasury samples of articles imported from foreign countries which are suspected of being dangerous to health; and such articles as are found by inspection and analysis to be dangerous to health are to be confiscated.

An appropriation of \$1,000 is made for tea culture, to investigate its adaptability to the Southern States.

The appropriation for the Division of Publications contains an increase of \$15,000, giving a total of \$101,660, including \$35,000 for Farmers' Bulletins. This is apart from the printing fund of the Department, which is provided in the general appropriation for printing. The Department's share of the latter is \$100,000 for the miscellaneous publications, and to this is added \$300,000 for the Yearbook.

The other items of the appropriation act are as follows: Office of the Secretary, \$88,150; Division of Statistics, \$145,160, an increase of \$5,000; Division of Botany, \$28,800; Division of Vegetable Physiology and Pathology, \$32,500, an increase of \$6,000; Division of Entomology, \$30,700; Division of Biological Survey, \$27,560; Division of Soils, \$26,300, including the \$10,000 for tobacco investigations; Division of Agrostology, \$20,100, an increase of \$2,000; Division of Pomology, \$16,000; Office of Experiment Stations, \$45,000, including \$12,000 for the Alaska stations; Nutrition Investigations, \$15,000; Public Road Inquiry, \$8,000; Division of Seeds, \$130,000; Experimental Gardens and Grounds, \$30,500, an increase of \$8,000; Domestic Sugar Production, \$7,000; Division of Accounts and Disbursements, \$16,300; Library, \$11,960; Museum, \$2,500; furniture, cases, and repairs, \$10,000; postage, \$2,000; contingent expenses, \$25,000.

In addition to the increased appropriations in many lines, the Department has been provided with a tract of land located near by to be used as a testing ground. This will afford facilities which the Department has long needed and will be a valuable acquisition to its equipment.

INVESTIGATIONS ON THE METABOLISM OF MILCH COWS.

OSCAR HAGEMANN, Ph. D.,

Professor at the Agricultural Academy, Poppelsdorf, Germany.

The theories concerning the processes in the animal body covered by the term metabolism have undergone many changes, and although much has been learned regarding them, they will undoubtedly be still further changed as investigation progresses and methods are improved. The earliest investigations of this sort were made with man. The weight of the food and drink was determined, as well as the weight of the material excreted in the urine, feces, and respiratory products. These investigations were carried on by Sanctorius and published in 1614.¹

Further progress was impossible until the science of chemistry had been elaborated, and this required 150 years. The most important advancement was in knowledge of the character of different gases. Van Helmont (1644) discovered carbon dioxid and also found that the air expired by man and animals was injurious. In 1757 Black identified carbon dioxid in respired air. Priestly and Scheele discovered oxygen in 1774-75; and Lavoisier established the relation between oxygen and combustion, and in 1777 published his classic investigations,² showing that when the vital processes take place in the human body oxygen is consumed and carbon dioxid excreted, in the same way that combustion takes place in a furnace. He held the opinion that with the aid of the food a fluid rich in carbon and hydrogen was formed in the lungs. This was constantly renewed, and united with the oxygen to form heat, water vapor and carbon dioxid being produced at the same time. Lavoisier also determined the effect of muscular work, food, and low temperature on the consumption of oxygen.

The investigations of Lavoisier and his associate, Berthollet, may be said to mark an epoch in animal metabolism. Lavoisier's theory of pulmonary combustion was incorrect, but more exact knowledge was impossible at that time, since the fact that the animal body is made up of cells was not discovered until many years after his death.

We are still further indebted to Lavoisier for the methods of elementary analysis. Among other things, this rendered possible the determination of the elementary composition of the food, urine, and feces,

² *Sur la respiration des animaux et sur les changements qui arrivent à l'air en passant par leur poulmon.*

and permitted investigations based on other data than the study of the gaseous excretory products.

Progress was hindered by the lack of a proper standard for comparing the processes which take place in the animal body. The development of organic chemistry and the isolation of a number of well characterized chemical compounds which occur in the food and excretory products furnished Liebig the foundation for his theories. He divided nutrients into nitrogenous (plastic) and nitrogen-free (respiratory) materials.

To Voit and his fellows belongs the credit of discovering the importance of protein as a nutrient, *i. e.*, that the animal requires daily in the food a definite amount of nitrogenous material in order to sustain life. The protein is broken down in the body at the same time the processes of combustion are carried on, and eventually the animal comes into nitrogen equilibrium. Nitrogen equilibrium can be reached when only protein is consumed, provided the amount is very large, but it can be attained with a much smaller amount if fat and carbohydrates are consumed at the same time. If the animal performs work, accumulates flesh and fat, or produces milk or wool, or nourishes a fetus, more protein must be consumed than for maintenance or an equivalent amount of nitrogen-free nutrients or both must be supplied. If work is performed nitrogen-free material is essential, if flesh is formed then protein is required.

Voit defined nutrients as materials which build and repair the animal body. This definition includes mineral matter and water.

In investigations which have proved most useful for an understanding of the processes of metabolism, the total income and outgo have been taken into account. The elementary composition of the food, urine, and feces has been determined, the respiratory products have been measured and analyzed, and finally the oxygen consumed has also been measured. The principal investigations along these lines were made by Bidder and Schmidt, Pettenkofer and Voit, Henneberg and his followers, Regnault and Reiset, and Pflüger and his associates.

It is interesting to note some of the changes in theories of animal feeding which have accompanied the growth of the knowledge of nutrition. In this connection two points have always been of importance and are important to day. The practical feeder (1) wishes to know the cost of a method of feeding and the profit it will return, and (2) he desires definite feeding standards or formulas which can be successfully followed. In the early part of the present century feeding stuffs were first examined on the basis of their content of protein, starch, gluten, sugar, gums, mineral matters, etc. As these materials were regarded as of equal value, it was customary to add them together and regard the sum as the measure of the nutritive value of the feeding stuff. The chemical methods followed were not exact, and for this and other reasons the system was of little value.

Boussingault called attention to the importance of the nitrogen content of feeding stuffs, and believed that this alone could be taken as a basis for estimating their value. On the other hand, Haubner showed that nitrogen-free material was useful for building up the animal body. Nathusius showed that the woody fiber was to a certain extent injurious; and Boussingault finally modified his theory so that on the basis of the nitrogen content feeding stuffs were divided into 4 classes: (1) Hay and straw, (2) roots and tubers, (3) oil-bearing seeds, and (4) grains, leguminous seeds, and oil cakes.

The attempt was also made to compare feeding stuffs in a practical or empirical manner by means of tables showing the so-called "hay values," or the hay equivalent of different materials. Thus it was said that 16 $\frac{2}{3}$ kg. hay equivalent was required per 1,000 kg. live weight for maintenance by cattle or sheep. If the food supplied more than this, each kilogram consumed in excess would produce a gain of 0.1 kg. body material or fetus or 1 liter of milk. However, one hay differs from another and other feeding stuffs also vary in composition, and as a result there were soon a considerable number of "hay value" tables from which it was impossible to select the correct one. An improvement was suggested by E. Wolff, who took account of the chemical composition of feeding stuffs and considered crude fiber as indigestible. Thus it was said that normal hay should contain 8.2 per cent of protein, 41.3 per cent of soluble nitrogen-free material, and 30 per cent of crude fiber, with a nutritive ratio of 1:5. This modification did not prove of much value since crude fiber is partially digestible, and, further, the soluble nutrients in different feeding stuffs have different nutritive values and different digestibility. The convenient theory of hay values was therefore abandoned and experiments were undertaken with different kinds of animals to learn how much protein, soluble nitrogen-free material, and fat must be fed for different purposes.

Grouven's normal feeding standards, which were published in 1862, were determined by this method. They were a great improvement on the tables of hay values, and superseded them. These standards were a series of formulas based on experiments depending in part on the general appearance of the subject, and on results of slaughter tests. Grouven also made many investigations, including digestion and respiration experiments, for the purpose of determining the nutritive value of a number of simple nutritive materials, such as sugar, starch, and dextrin.

A curious theory was devised by Enzmann in 1866.¹ He determined the ratio of carbon to nitrogen in different feeding stuffs, designating it the "specific carbon content," and on this basis arranged materials as follows: Rice straw 117, potatoes 34, hay 27.4, red clover hay 17.4,

¹ Landw. Vers. Stat., 8 (1866), pp. 309, 320. For earlier work see *Die Ernährung der Organismen besonders des Menschen und der Thiere im hungernden Zustande*. Dresden: C. C. Meinhold & Söhne, 1856.

peas 11, cows' milk 8, lupines 7.8, lean meat 4, blood 3.5, protein 3.4. He taught that the food must supply an animal with the specific carbon value suited to its age. Thus, a sucking calf required a specific carbon value of 8, since the value of milk was 8. The value was greater for older animals. For cattle, horses, and sheep it was between 24 and 44, for swine 26, and for milch cows 24. This theory was based entirely on speculation and has never been followed practically.

Finally an attempt was made to learn how much of the different feeding stuffs was required by trusting the instincts of the animals when given the choice of materials. Thus, a milch cow was given the choice of oil cake, fodder beets, hay, and straw. The amount of each consumed was determined. Such investigations were made by Haubner and he soon showed that the method was too costly to be of any practical benefit.

About 1860 Bischoff and Voit made their classic investigations on nitrogen equilibrium and formulated the laws of growth for Carnivora. Instead of depending on the body weight to show whether a ration was sufficient, the nitrogen excreted in the urine was determined, and further, the excretion of carbon dioxide in the respiratory products was measured by a suitable respiration apparatus. An animal was said to be in equilibrium when the nitrogen and carbon in the excretory products equaled the amount consumed in the food, due account being taken of the amounts of carbon and nitrogen lost in epithelial cells, sweat, mucus, hair, nails, hoofs, and horns. These investigations were at first made with Carnivora only, mainly with dogs and cats, but later were carried on with man. It was much simpler to study the laws of nutrition with Carnivora than Herbivora since their diet is comparatively simple, the urine is easy to collect and analyze, when fed once a day the feces are excreted daily, and the food does not remain in the intestinal tract longer than 24 hours. Such experiments with Herbivora, and especially with ruminants, are attended with much greater difficulties. Nevertheless Henneberg, Stohmann, Gronven, and others have shown that with ruminants also the general laws of nutrition hold good. Such investigations are being carried on at the present time, and have furnished a large amount of useful information. However, much still remains to be studied.

E. Wolff has devoted many years to determining the coefficients of digestibility of feeding stuffs by sheep and horses. Külm in Möckern and his successor, Kellner, and many others have devoted much time to methods of analysis of feeding stuffs and methods of metabolism experimenting, with a view to establishing a rational basis for animal feeding. A number of the agricultural experiment stations have devoted much attention to these subjects and have made many determinations of the digestibility of different foods by various animals.

Recently in addition to proximate analyses of the food and feces and determinations of nitrogen in the urine, calorimetric experiments have been undertaken, and the balance of income and outgo of energy

attempted in addition to that of nitrogen and carbon. Samples of food, urine, and feces are burned in a Berthelot bomb in an atmosphere of oxygen under pressure. In this way the total energy—*i. e.*, heat of combustion—may be determined. The fuel value of the food less the fuel value of the feces gives the fuel value of the food digested. This amount, less the fuel value of the urine, gives the fuel value available for the body. If the income of energy is greater than the outgo, the ration is more than sufficient for maintenance. Kellner published the results of such experiments with cattle about 2 years ago. However, as early as 1880 he called attention to the importance of calorimetric investigations of this nature.

Another important factor upon which information is essential is the amount of energy which is expended in digesting food. An idea of its importance may be gathered from an experiment which was undertaken by Zuntz and the writer with a horse. It was found that the horse digested 391 gm. of fiber-free nutrients from a kilogram of hay and 615 gm. from a kilogram of oats. Therefore, according to the usual method of comparison, hay : oats :: 391 : 615, or in round numbers, as 2 : 3. This deduction, however, is not warranted. A kilogram of hay requires for chewing and digesting an expenditure of energy equivalent to 209 gm. of fiber-free nutrients, and a kilogram of oats an amount equal to 124 gm. This energy is eventually transformed into heat and supplies wholly or in part the warmth required by the animal body, so that as regards maintenance hay and oats may truly be said to stand in the ratio of 2 : 3. But if the ration is in excess of the amount required for maintenance, for instance, if work is to be performed, then the ratio is as follows: Hay : oats :: 391 — 209 : 615 — 124, or 182 : 491, or in round numbers 1 : 2.7. That is, 2.7 kg. instead of 1.5 kg. of hay is equal to 1 kg. of oats.

EXPERIMENTAL METHODS.

In metabolism experiments it is absolutely necessary to collect the urine and feces and determine the amount and composition of each. The nitrogen in the urine is always determined, and often the carbon, hydrogen, and mineral matter. It is usually necessary to dry the feces before analysis. The same determinations are then made as in the urine, and, in addition, proximate analyses corresponding to the determinations made in the food. In the case of large domestic animals, milch cows, for instance, it would be very inconvenient to retain all the feces for analysis, since they may amount to 20 or 30 kg. daily. Therefore aliquot samples should be taken each day and dried and united for analysis. The materials excreted each day in the feces can then be calculated. In the case of steers, the collection of the urine is a comparatively simple matter, and special apparatus has been devised for this purpose. In the case of cows, the usual plan is to watch the animals day and night and collect the urine directly in suitable vessels. Sometimes animals are kept in a stall with a grating in the floor through

which the urine can flow. It is then collected, together with the water used to rinse the floor and receptacles. In experiments with sheep and swine the feces are often collected in a suitable sack attached to the animal, though this precaution is not always taken. The difficulty of separating and collecting the urine and feces with milch cows perhaps accounts for the relatively small number of metabolism experiments with them.

An experiment of 5 days' duration was made by Voit in Munich, and one of 8 days' duration by Fleischer in Hohenheim. In both cases the excretory products were collected in suitable vessels by the assistants watching the cows. In 1869 Kühn and Fleischer, at Möckern, devised an apparatus for experiments with cows which permitted a satisfactory collection of the urine, but did not provide for the collec-

FIG. 15.—Apparatus for use in digestion experiments with cows.

tion of the feces. In 1894 the writer devised apparatus for use in experiments with cows which insures the separation and collection of the urine and feces. It is attached to the cow by means of a band around the body. A system of pulleys and bands holds the apparatus in position when the cows are lying down or standing. The device is illustrated in the accompanying figures.

In metabolism experiments it is essential to determine the amount of urine and feces excreted per day, rather than the total amount excreted, since this alone offers a means of judging of the cleavage processes which take place in the body. In the case of experiments with dogs each day's urine may be easily collected by means of a catheter, but with large animals, such as steers, this is hardly practicable. In the case of man and some animals the feces may be separated with char-

coal, cork dust, or berry seeds taken with the last meal before and the first meal after the period under investigation. In experiments with *Herbivora*, owing to the lack of suitable methods of separating the feces it is customary to delay the collection of the excretory products until the food under investigation has been consumed for from 2 to 3 weeks, since it may be assumed that digestion and excretion then take place regularly, and that the stomach and intestinal tract of the animal at a given time will contain the same amount of material. It is essential that the animals be fed regularly and given like amounts of food and water each day. In the case of the urine it is assumed that under ordinary circumstances no considerable quantity is retained in the bladder.

FIG. 16.—Parts of apparatus for use in digestion experiments with cows.

A metabolism experiment with milch cows should be conducted as follows: A preliminary period of 3 weeks should precede the experiment proper. The floor of the stall is then thoroughly cleaned. The device described above is attached to the cow and the time noted at which the last urine and feces were excreted. Suppose, for instance, that urine was excreted at 1.20 p. m., March 25, 1898, feces at 2.50, and the apparatus was attached at 3 p. m. The urine and feces are then collected for from 8 to 14 days and the time at which the experiment is discontinued is noted, together with the time of excretion of the last urine and feces. Suppose this in the case of urine to have been 4.40 p. m. and in the case of feces 2.30. Then the urine has been collected for 10 days $3\frac{1}{2}$ hours and the feces for 10 days lacking one-third of an hour. In calculating the daily excretion suitable correction must be made for fractional days.

Proper means must be taken for preventing fermentation of the excretory products when they are retained for analysis. To this end the feces should be removed as soon as possible from the bag in which they are collected, and should be weighed, sampled, and dried at once. In winter the cold weather prevents the fermentation of the urine. In summer a known quantity of preservative material—for instance, sulphuric acid, formic aldehyde, or thymol—may be added to the urine. The apparatus for collecting the urine must be rinsed at least once in 48 hours with a disinfecting solution (10 per cent formic aldehyde), and afterwards with pure water. When only the nitrogen in the urine is determined it is a matter of indifference which preservative is used. If the carbon is also determined then the use of sulphuric acid or cold storage must be resorted to, since both formic aldehyde and thymol contain carbon. If the mineral matter is also to be determined then sulphuric acid can not be used and a low temperature is the only method available.

Care must be taken that all the food is eaten or that the uneaten residue is weighed. The same precaution applies to water also.

During the preliminary period the weight of the animal should be accurately determined daily. During the experiment proper this factor may also be determined if the urine and feces are collected as soon as they are excreted. However, it is not a matter of great importance to determine the weight during this period unless it is long. When the weight remains constant for 2 or 3 months, or when it slowly increases or diminishes during such a period, this factor is of importance in drawing deductions. Otherwise the variations in water content of the intestinal tract, and hence the excretion of a larger or smaller quantity of feces on a given day, render this determination unreliable. Aside from such irregularities an animal may lose fat and flesh daily—that is, be in a condition of partial starvation—while the body weight remains constant or even increases. This is the case when the fatty tissue and protein (cells and cell contents) are broken down and replaced by water. In other words, if the experimental period is short a loss of body material may be covered by the large gain of water. The converse is also true. An animal poor in flesh but with a high water content may gain flesh and fat and at the same time lose weight owing to a diminution of the water in the tissues.

ANALYSIS OF THE MATERIALS.

In the analysis of the total food, the uneaten residue, and the feces it is important to determine the amount of sand and pure ash (including silica) in addition to the total ash. The sand mixed with the food passes through the animal undigested, and if the amount consumed is recovered it is an indication that the analytical work is to be depended upon.

Organic material in food and excretory products is made up of nitrogenous and nitrogen-free substances. The former include protein,

amids, alkaloids, and other chemical bodies of little importance in nutrition. The nitrogen-free material includes fat, soluble carbohydrates, and crude fiber. The methods employed in determining these substances are well known. Those employed by the writer are described at length by König in his book on agricultural and commercial analysis.

The estimation of water is of especial importance. If the material is dried in the air at 105 to 110° C., the results may be too high, owing to the expulsion of too much water and in some cases to an oxidation of the fat. The water driven off under these conditions may be of 4 kinds: (1) The hygroscopic water on the surface of the substance and in the capillary spaces or the residue from the former cell fluid, (2) water which held the same relation to the separate constituents of the cell as the water of crystallization of an inorganic salt, (3) water formed at this temperature by the union of oxygen and hydrogen within the organic molecules, and (4) water formed by the action of the oxygen of the air on the hydrogen of the substance. It is possible also that some of the carbon may be oxidized to carbon dioxide.

The term "dry matter" can properly be applied only to substances from which water included under 1 and 2 has been removed. It has been the writer's practice to dry all materials in a current of dry illuminating gas. Drying need not be continued longer than 24 hours at 70° to attain constant weight, provided a sufficient quantity of gas can be drawn through the apparatus without increasing the pressure. Many substances—oil cakes, for instance—lose material other than water when heated to 70°. In such cases the drying must be continued for more than 24 hours at from 40 to 50°. The receptacle in which the substance to be dried is weighed consists of 2 parts which fit together very closely, so that moisture is not absorbed during weighing. It is a matter of the utmost importance in metabolism experiments to estimate the dry matter in food, urine, feces, milk, etc., by a uniform method. Urine and milk may easily be dried in 3 days over a sufficient quantity of sulphuric acid (100 times as much as the dry matter), if mixed with kaolin, pumice stone, or sand.

Sampling for analysis is a matter of great importance. This is comparatively simple with milk, urine, and ground concentrated feeding stuffs, such as cotton-seed meal or ground peanut cake. It is more difficult in the case of feces and such materials as whole or coarsely ground grains. Two samples at least should be taken of such materials. Sampling is most difficult in the case of coarse fodders, and it is advisable to take 3 samples. In sampling hay, straw, etc., the material may be divided into bundles, and each bundle passed through a cutting machine, like portions being retained from each bundle. These portions should be thoroughly mixed and samples for analysis taken from the mixture.

Suppose 6 metabolism experiments are to be made with 2 cows. Each experiment requires a month. The 2 cows in 6 months would

require about 2,200 kg. of hay and 750 kg. of straw. Therefore this amount of material must be procured and so preserved that its moisture content will not be changed during the experiment. Three to 5 per cent of the material (66 to 110 kg. of hay and 22 to 38 kg. of straw) should be taken for sampling. The hay or straw should be spread out in an even layer on paper or suitable material and portions taken here and there. These portions should in the same way be mixed and spread in an even layer and from the mixture final samples taken for analysis.

In experiments with cows it is necessary to determine the nitrogen in the fresh feces, since nitrogen is lost if the material is dried. The Kjeldahl method is used for this purpose. The fat may be determined in the usual way, using ether distilled over sodium. The crude fiber should be determined by heating the substance in autoclaves at 3 atmospheres pressure in glycerin-sulphuric acid (20 gm. sulphuric acid to 1 liter glycerin).

An elementary analysis may be combined with determination of the heat of combustion of different materials by collecting the resulting gas in the bomb, measuring it, and analyzing small portions.

BALANCE OF INCOME AND OUTGO.

In accurate metabolism experiments, in addition to the determinations noted above, it is necessary to measure the carbon dioxide excreted in the breath. It is also desirable to measure the oxygen consumed from the air, although fairly accurate results may be obtained when only the carbon dioxide is measured, as is done with the Pettenkofer respiration apparatus.

When protein, fat, and carbohydrates are the only materials utilized in the animal body, as is the case with Carnivora, determining the outgo of carbon in addition to the nitrogen in the urine is sufficient. Thus, in an experiment with a dog the urine was found to contain 17 gm. of nitrogen and 14.3 gm. carbon and the respired air 160 gm. carbon per day on a diet of protein and fat in one instance and of fat and starch in another. As protein contains 16 per cent of nitrogen and 53 per cent of carbon—*i. e.*, in the proportion of 16 to 53—the 17 gm. of nitrogen would call for 56.3 gm. carbon. Of this, 14.3 gm. was found in the urine, leaving 42 gm. of carbon to be ascribed to the protein broken down in the body. Since 160 gm. carbon was excreted in the respired air, 118 gm. (160-42) must have been derived from starch or fat. Animal fat is fairly uniform in composition, containing in round numbers 77 per cent carbon, 12 per cent hydrogen, and 11 per cent oxygen, while starch contains 44.4 per cent carbon, 6.2 per cent hydrogen, and 49.4 per cent oxygen; that is, 153 gm. fat or 266 gm. starch would furnish 118 gm. carbon.

If the dog is fed with both fat and starch in addition to protein, it is not possible to calculate the amount of fat and of starch broken down in the body by determining the amount of carbon dioxid excreted in addition to the nitrogen in the urine. In this case the amount of oxygen consumed must be known in addition. This may be calculated. It is not probable that the animal body can use protein when fed in connection with fat and starch more economically than protein from its tissues when fasting. Voit found that the organic matter excreted in the urine of a fasting dog was made up of 25.5 per cent carbon, 6.4 per cent hydrogen, 34.4 per cent nitrogen, and 33.7 per cent oxygen. If 100 gm. of protein were broken down in the body 16 gm. of nitrogen would be found in the urine, together with carbon, hydrogen, and oxygen. The data for calculating the amount of oxygen required for the combustion of protein and the amount of carbon dioxid produced from protein are therefore available. Suppose that 100 gm. protein is consumed and 46.6 gm. organic matter excreted in the urine. Then—

100 gm. protein consumed	= 53.0 gm. C, 7 gm. H, 16 gm. N, 23.0 gm. O, 1 gm. S	
46.6 gm. organic material in urine =	11.9 gm. C, 3 gm. H, 16 gm. N, 15.7 gm. O,	
Remainder	= 41.1 gm. C, 4 gm. H,	7.3 gm. O, 1 gm. S

The C, H, and S will be oxidized to CO_2 , H_2O , and SO_3 . The oxidation of 41.1 gm. C would produce 150.7 gm. CO_2 . This would require 109.6 gm. O; 4 gm. H would produce 36 gm. H_2O and require 32 gm. O; 1 gm. S would produce 2.5 gm. SO_3 , requiring 1.5 gm. O, or a total of 143.1 gm. of oxygen. Deducting from this amount 7.3 gm. O furnished by the food in excess of the amount excreted in the urine, leaves 135.8 gm. of oxygen as the amount which must be taken by the body from the inspired air. As noted above, the expired air contained 150.7 gm. CO_2 . One liter of carbon dioxid weighs 1.96633 gm. and 1 liter of oxygen 1.43003 gm. at 760 mm. mercury pressure. The respiratory quotient—that is, the ratio of carbon dioxid produced to oxygen consumed—would be as follows:

$$\frac{\text{CO}_2}{\text{O}_2} = \frac{150.7 \div 1.96633}{135.8 \div 1.43003} = 0.807$$

If 17 gm. of nitrogen were excreted in the urine, as mentioned above, then the amount of carbon dioxid produced by the combustion of protein in the body would be as follows:

$$\frac{17 \times 150.7}{16} = 160.1 \text{ gm. CO}_2 \text{ (containing 43.7 gm. C).}$$

The amount of oxygen necessary would be:

$$\frac{17 \times 135.8}{16} = 144.3 \text{ gm. O.}$$

Supposing the animal took 500 gm. of O from the air and excreted 160 gm. CO_2 in the breath, the amount of carbon which must have

been derived from some substance other than protein—that is, from fat and carbohydrates—is shown as follows:

160 gm. C (excreted in breath) — 43.7 gm. (derived from protein) = 116.3 gm. (derived from fat and starch).

500 gm. O (amount consumed) — 144.3 (amount necessary for oxidation of protein) = 355.7 gm. O (amount for oxidation of carbon from fat and starch).

The proportion of fat and starch burned in the body may be determined by studying the respiratory quotient. Ordinary animal fat has the following percentage composition: 76.54 carbon, 12.01 hydrogen, 11.45 oxygen. When 100 gm. fat is burned 11.45 gm. oxygen and 1.43 gm. hydrogen unite to form water, and there remain 10.58 gm. hydrogen and 76.54 gm. carbon. These require 84.64 gm. and 204.11 gm. oxygen, respectively, or a total of 288.75 gm. for complete combustion, 280.65 gm. CO₂ being produced. This oxygen must be derived from the air. The respiratory quotient would therefore be

$$\frac{280.65 \div 1.96633}{288.75 \div 1.43003} = 0.7069$$

Starch has the formula (C₆H₁₀O₅)_x. Its molecular weight is therefore some multiple of 162. The oxygen in the starch molecule is sufficient for a complete combustion of the hydrogen; therefore only an amount sufficient for the combustion of the carbon need be taken from the air. The carbon in 162 gm. of starch would require 192 gm. of oxygen for its combustion and produce 264 gm. carbon dioxide. Therefore the carbon in 100 gm. would require 118.5 gm. oxygen, producing 163 gm. carbon dioxide. The respiratory quotient when starch is burned is therefore 1. If a respiratory quotient of 1 is found in an experiment, then starch alone is burned in the body. A respiratory quotient of 0.7069 shows that fat only is burned. If the respiratory quotient is between these values, it indicates the combustion of a mixture of fat and starch.

The amount of oxygen necessary for combustion may be computed as follows:

Let A = total O used, B = CO₂ produced, and X = O necessary for oxidation of fat. Then A — X = O available for oxidation of starch; and X × 0.7069 + (A — X) × 1 = B (the CO₂ produced).

In the concrete example cited above there were 116.3 gm. of carbon (equal to 216.9 liters of carbon dioxide) and 355.7 gm. (equal to 248.7 liters) of oxygen remaining to be accounted for by combustion of fat and starch. The respiratory quotient would therefore be 0.872.

Substituting the proper values in the above equations would give the following:

0.7069 X + 248.7 — X = 216.9. Then X = 108.5, the oxygen necessary for oxidation of fat; and 248.7 — 108.5 = 140.2, the oxygen necessary for oxidation of starch.

From the above data the metabolism of energy in the animal body can be calculated. One gram of protein burned in a calorimeter produces 5.711 calories (mean of Berthelot and Stohmann's determinations). Combustion in the animal body is less complete since nitrogen is excreted largely in the form of urea, therefore less energy is produced. According to Rubner 1 gm. of dry matter of ash-free protein of tissue burned in the body of a fasting animal yields 4.4 calories. Provided the animal is amply nourished, substances containing more carbon and having a higher fuel value than urea are excreted in the urine, therefore the energy available from the combustion of protein is still less. The true value in such cases can not be calculated with certainty, but must be determined by accurate investigation in the individual experiments. In most cases it is sufficiently accurate to assume that 1 gm. of protein yields 4.1 calories when burned in the body.

The heat of combustion of a gram of fat is 9.5 calories and of 1 gm. of starch 4.18 calories. As noted above, the combustion of 100 gm. of fat requires 288.75 gm. or 201.9 liters of oxygen. Each liter of oxygen utilized for the combustion of fat produces 4.7 calories ($950 \div 201.9 = 4.7$); 100 gm. of starch requires for oxidation 118.5 gm. or 82.9 liters of oxygen. Therefore each liter of oxygen used in the oxidation of starch produces 5 calories ($418 \div 82.9 = 5$).

In the example cited above the total energy produced would be 1,646.6 calories, calculated as follows:

	Calories.
$\frac{100 \times 17}{16} = 106.25$ gm. protein burned in the body. 106.25×4.1	= 435.6
The oxidation of fat requires 108.5 liters oxygen. 108.5×4.7	= 510.0
The oxidation of starch requires 140.2 liters oxygen. 140.2×5	= 701.0
Total.....	1,646.6

In this computation no account is taken of the fact that in addition to protein other nitrogenous materials, amids for instance, were consumed, which also produce nitrogenous compounds in the urine but of less fuel value than the compounds derived from protein. Further, when large quantities of fat and starch are consumed fat will be stored in the body. The amid nitrogen in the urine may be treated as nitrogen derived from protein without serious error, since the assumption is made that 46.6 gm. organic material in the urine is derived from the cleavage of 100 gm. protein, and further since the fuel value of protein is assumed to be 4.1 calories per gram. For very accurate investigations, however, the above factors can not be used and actual determinations of the values must be made.

If the food is very abundant the formation of fat from starch is accompanied by cleavage of carbon dioxide from the starch molecule. Deducting the values for the oxidation of protein the respiratory quotient in the case becomes greater than 1. That is, the total quantity of oxygen available for the oxidation of nitrogen-free material should be assumed

to be used for the oxidation of starch. The excess of carbon dioxide must be attributed to the formation of fat from starch. These facts are more clearly brought out in the following equation:

100 gm. fat will yield 950 calories.

100 gm. starch will yield 418 calories.

The greatest possible quantity of fat which can be formed from 100 gm. starch is 44, since $418 \div 9.50 = 44$.

100 gm. starch contains.....	44.44 gm. C, 6.18 gm. H, 49.58 gm. O
44 gm. fat contains.....	33.68 gm. C, 5.28 gm. H, 5.04 gm. O

Difference.....	10.76 gm. C, 0.90 gm. H, 44.54 gm. O
-----------------	--------------------------------------

For oxidation there is required 28.69 gm. O + 7.20 gm. O = 35.89 gm. O.

The oxidation products are: 39.15 gm. CO₂ and 8.10 gm. H₂O.

Excess: 8.45 gm. O. ($44.54 - 35.89 = 8.45$.)

This quantity of oxygen is available for the oxidation of further quantities of starch. It would oxidize 7.13 gm. starch ($162 \div 192 \times 8.45 = 7.13$). This would yield 29.8 calories ($7.13 \times 4.18 = 29.8$) and 11.62 gm. carbon dioxide. That is, from 107.13 gm. starch 44 gm. fat can be produced, together with 51.7 gm. or 26 liters carbon dioxide and 29.8 calories. In other words, when the respiratory quotient is greater than 1, each liter of carbon dioxide in excess of the quantity of oxygen required is equivalent to 1.694 gm. fat and 1.15 calories.

[Concluded in next number.]

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

The oil of corn, C. G. HOPKINS (*Jour. Amer. Chem. Soc.*, 20 (1898), No. 12, pp. 948-961).—The author reports a systematic study of corn oil obtained partly by extraction and partly from starch and glucose factories. Determinations were made of the specific gravity, melting point, iodine absorption, and oxygen absorption of the oil and of the content of lecithin, cholesterol, total fatty acids, volatile acids, and the separate fatty acids. The method of operation is described in each case. The total fatty acids were found to constitute 93.57 per cent of the oil. A summary of the composition of corn oil, as found in this investigation, is as follows:

<i>Composition of corn oil.</i>	
	Per cent.
Cholesterol	1.37
Lecithin	1.49
Stearin (?)	3.66
Olein	44.85
Linolin	48.19
Total	99.56

It was found that corn oil does not take up any oxygen at room temperature, but when heated in a water oven changes in weight were noticed which have an important bearing on the determination of water in corn.

“The first action of air upon the hot oil is evidently the direct addition of oxygen; but after 2 or 3 days the oil began to turn noticeably darker in color and finally to lose weight, evidently due to a secondary reaction which effects some decomposition of the oil with formation of volatile products.”

Proceedings of the eleventh convention of the Association of Agricultural Experiment Stations in the German Empire (*Landw. Vers. Stat.*, 51 (1898), No. 1, pp. 15-44).—This reports, among other things, the action of the association on methods of analysis of Thomas slag and of examining seeds, and includes discussions on the preparatory training of station assistants, the allowable amount of perchlorate

in nitrate of soda, and changes in laws. Comparative tests by 19 stations of the molybdic and Böttcher citrate methods for determining the citrate-soluble phosphoric acid in Thomas slag are reported. As a result of this work, the citrate method was made optional, although in cases of dispute Wagner's molybdic method is to be used.

By applying the Loges method the Halle Station found in 107 samples of nitrate of soda from 0.27 to 5.64 per cent of perchlorate, averaging 0.94 per cent. The general occurrence of this substance in nitrate was shown by reports from other analysts. P. Wagner briefly reported results of pot experiments with different amounts of perchlorate on oats and rye. He found that the rye plants ceased to grow when the nitrate of soda used contained 12 per cent of perchlorate; the oat plants died when the amount reached 18 per cent.

No change was made in the methods of seed testing.

It seemed to be the consensus of opinion that the best preparation for station assistants consists in a good, general training in analytical chemistry, the necessary technical skill required being easily acquired in the laboratory.

A new solvent for distinguishing the phosphoric acid in various phosphates, W. HOFFMEISTER (*Landw. Vers. Stat.*, 50 (1898), No. 5-6, pp. 363-379).—The author claims that humic acid furnishes a more reliable means of distinguishing between different phosphates than the citrate solutions commonly used. The humic acid is prepared as follows: Extract wood lignin with ammonia vapor, precipitate the humic acid in the ammoniacal solution with dilute hydrochloric acid, collect the precipitate on a filter, wash and dry. Extract with alcohol and again dissolve the humic acid in ammonia, precipitate, wash, and dry.

The method proposed for the examination of the phosphate is as follows: Dissolve 15 gm. of the humic acid in dilute ammonia¹ and pour the solution into a 2-liter flask containing some sand. Add 5 gm. of the phosphate and 1 liter of water; shake the contents of the flask and pass a moderately rapid current of carbon dioxide through the solution for 12 days, adding ammonia¹ frequently; pour off the solution; wash the sand; combine the wash water with the solution previously poured off; make up to a definite volume; filter, and evaporate four-fifths of the filtrate to dryness with the addition of hydrochloric acid; treat the residue with water containing a little hydrochloric acid; filter, wash, and make up the filtrate to 100 cc. Use portions of this solution for the determination of phosphoric acid, etc.

A slag containing 16.7 per cent of citrate-soluble phosphoric acid according to Wagner's method gave 10.43 and 10.38 per cent soluble in humic acid by the author's method. In bone meal and fermented bone meal 1.01 and 1.48 per cent of phosphoric acid respectively were dissolved in the humic acid. When the slag was very finely ground the two methods gave practically identical results—18.53 per cent by the

¹ The amount of ammonia to be used is not stated.

Wagner method and 18.48 and 18.45 by the author's method—thus showing the great importance of manufacturers supplying slag in the finest possible form.

Humic acid dissolved 95.8 per cent of the phosphoric acid in very fine ground slag, 30.38 per cent of that of Redonda phosphate, and 43.3 per cent of that in bone precipitate.

The determination of potash as perchlorate, F. S. SHIVER (*Jour. Amer. Chem. Soc.*, 21 (1899), No. 1, pp. 33-42).—The solution of potash, after freeing from sulphuric acid and nonvolatile acids, is evaporated in a porcelain dish with an excess of perchloric acid until all odor of hydrochloric or other volatile acids has disappeared, and the white fumes of perchloric acid begin to appear. The sirupy solution is then treated with alcohol containing 0.2 per cent of perchloric acid, the precipitate washed by decantation, transferred to a Gooch crucible, washed with pure alcohol, dried, and weighed. The method is proposed as a check upon the commonly employed platinum chlorid method.—L. H. MERRILL.

A source of error in the determination of nitrogen in Chile salt-peter by the Ulsch method, L. BRANDT (*Chem. Ztg.*, 23 (1899), No. 3, p. 22).—The author discovers an impurity in the iron used for his determinations in the form of an organic nitrogen compound, the nitrogen of which is converted into ammonia when the iron and sulphuric acid are brought together in the process. The error thus occasioned, he finds, amounts to as much as 0.8 per cent, when 0.5 gm. of Chile salt-peter is used in the determination. He announces this discovery to put other analysts on their guard.—J. T. ANDERSON.

Some errors in the determination of nitrogen, C. G. HOPKINS (*Jour. Amer. Chem. Soc.*, 20 (1898), No. 12, pp. 961-965).—Two common sources of error were investigated, (1) the loss of ammonia in titrating in an open vessel, and (2) the loss of ammonia from the receiving flask in case there is not sufficient acid above the end of the delivery tube to neutralize all of the ammonia distilled over. In the first case it was found that when titration requires from 3 to 5 minutes the error from loss of ammonia from the standard solution may become an important factor, the total variation in the two series of experiments amounting to 0.6 cc. or 3 per cent of the ammonia required. In the second case the loss of ammonia was found to vary with the depth to which the delivery tube of the condenser dipped into the standard acid, in some cases amounting to a considerable proportion of the amount of ammonia theoretically required.

Report on an investigation of analytical methods for distinguishing between the nitrogen of proteids and that of the simpler amids or amido-acids, J. W. MALLETT. **Separation of proteid bodies from the flesh bases by means of chlorin and bromin**, H. W. WILEY (*U. S. Dept. Agr., Division of Chemistry Bul.* 54, pp. 30).—In the first part the classes of nitrogenous constituents in food and the

plan of the investigation are discussed, and a description is given of the various methods which have been proposed for the separation of proteid matter in animal products, with investigations of these methods.

“By a happy modification of the phospho-tungstic acid method he has greatly improved this process, and shown how a practical separation of the flesh bases from the other nitrogenous substances can be effected by this reagent. The flesh bases are to some extent precipitated by the new form of the reagent proposed by Professor Mallet, but they are brought into a soluble state by the addition of water and heat, so that a practically complete separation of them is effected. This process, together with the use of tannic acid for the separation of peptones, leaves little to be desired in securing a practically complete separation of the nitrogenous matters.”

In the second part H. W. Wiley describes in detail the method of separating proteid bodies from the flesh bases by the use of hot water followed by chlorine or bromine, which has recently been investigated in the laboratory of the Division of Chemistry and applied in a series of analyses of flesh products. The application of the bromine method to commercial meat extracts is discussed, and the factors for the calculation of total nitrogen are considered.

Investigations on the effect of the quality of the ether on the results of fat determinations in feed stuffs, T. METHNER (*Chem. Ztg.*, 23 (1899), No. 5, pp. 37, 38).—Results are given which were obtained with the use of (1) ether purified by metallic sodium in the prescribed way, (2) ether thus purified plus varying amounts of absolute alcohol, and (3) ether which had been allowed to stand over caustic lime for 3 weeks and then distilled. The author concludes from these results that alcohol, in the amounts used, has no considerable influence on the amount of extract obtained, and that ether, purified by caustic lime, is pure enough for practical purposes.—J. T. ANDERSON.

A condenser for extraction work, C. G. HOPKINS (*Jour. Amer. Chem. Soc.*, 20 (1898), No. 12, pp. 965, 966, fig. 1).—This condenser has the water tube inside, instead of in the usual form of a jacket, both the inlet and outlet being at the top of the condenser and the inlet tube extending to the bottom of the water tube. It is intended for use in fat extraction apparatus in place of the ordinary condenser, “mainly to avoid the constant trouble of having atmospheric moisture condense upon the outer surface . . . and run down over the extraction apparatus.” The condenser may also be used in ordinary distillation and is less likely to break than the ordinary condenser.

Researches on chemistry and physiology, applied to agriculture, A. PETERMANN (*Recherches de chimie et physiologie, appliquées à l'agriculture*. Brussels: O. Mayoly and J. Audietre; Liege: C. Desoer; Paris: G. Masson, 1898, vol. 3).

Text-book of physiological chemistry, O. HAMMARSTEN (*New York: John Wiley & Sons, 1898, pp. 705*).—Authorized translation from the third German edition by J. A. Mandel.

The estimation of manganese by means of potassium permanganate, F. W. DAW (*Chem. News, 79 (1899), No. 2043, p. 25*).—See also note by H. Bearley in *Chem. News, 79 (1899), No. 2044, p. 47*.

Formaloxin as a reagent for detecting small quantities of copper, A. BACH (*Compt. Rend. Acad. Sci. Paris*, 128 (1899), No. 6, pp. 363-365).

Analytical studies of flour of different sorts, D. A. VAN BASTALAER (*Ann. Pharm.*, 1898, pp. 193-200, 246-256; *abs. in Ztschr. Untersuch. Nahr. u. Genussmitl.*, 2 (1899), No. 1, p. 156).—New reactions with picric acid, alcohol, tincture of iodine, and potassium hydroxide solution are described.

Detection and determination of gelatin in gums and food materials, A. TRILLAT (*Bul. Soc. Chim. Paris*, 19 (1898), No. 24, pp. 1017-1019).

Contribution to the determination of fat in milk, M. KÜHN (*Milch Ztg.*, 27 (1898), No. 48, pp. 755-757; 49, pp. 771-774; 50, pp. 789-791; 51, pp. 807, 808; 52, pp. 823-825; 53, pp. 835-837).—A comparison of the Adams and various simpler methods for determining fat.

Pure or adulterated butter, P. VIETH (*Milch Ztg.*, 27 (1898), No. 53, pp. 833-835).—This deals with the reliability of the Reichert-Meißl number as a means of determining adulteration of butter. Studies by the author in England in 1889-1891, and recently at the Dairy Institute at Hameln, are cited to show that normal butter may be so low in volatile fatty acids as to condemn it as adulterated, if this determination alone is depended upon. Caution is urged, but no specific means of detecting adulterated butter are suggested.

The analytical constants of American linseed oils, A. H. GILL and A. C. LAMB (*Jour. Amer. Chem. Soc.*, 21 (1899), No. 1, pp. 29, 30).—The constants are given of 9 of the principal brands of linseed oil found upon the market.—L. H. MERRILL.

Examination of water: Chemical and bacteriological, W. P. MASON (*New York: John Wiley & Sons; London: Chapman & Hall*, 1899, 1. ed., pp. V + 135).

The microscopy of drinking water, G. C. WHIPPLE (*New York: John Wiley & Sons; London: Chapman & Hall*, 1899, 1. ed., pp. X + 338).

Wheat oil, G. DE NEGRI (*Chem. Ztg.*, 22 (1898), No. 92, p. 976).—A study of the oil expressed from the germ of wheat.

Short handbook of oil analysis, A. H. GILL (*Philadelphia: J. B. Lippincott Co.*, 1898, pp. 139).

A method of analyzing natural and artificial organic coloring matters, A. G. ROTA (*Chem. Ztg.*, 22 (1898), No. 44, pp. 437-442; *abs. in Analyst*, 24 (1899), Feb., pp. 41-47).—The method covers the separation of different coloring matters and their detection. The abstract is quite full.

Apparatus for the saponification of fats, oils, etc., J. G. ANNAN (*Chem. News*, 79 (1899), No. 2045, p. 51, fig. 1).—This consists of an ordinary Erlenmeyer flask fitted with a cork with 2 holes, one to carry the condenser which is mostly within the flask, and the other to be closed by a piece of glass rod. The apparatus requires no attention after the saponification has been started. It is believed to have "some advantages over that generally used for saponifications, more especially in the determination of Koettstorfer's figure."—C. B. WILLIAMS.

Improved apparatus, J. C. SAMMIS (*Jour. Amer. Chem. Soc.*, 21 (1899), No. 1, pp. 42-45, figs. 2).—An improved burette and an electric heater for use in ether extraction are described.—L. H. MERRILL.

Automatic burettes, A. W. STOKES (*Analyst*, 24 (1899), Jan., pp. 4-6, figs. 3).—The requirements of a perfect automatic burette are outlined, and several complex forms described.—E. B. HOLLAND.

An automatic burette, H. D. RICHMOND (*Analyst*, 24 (1899), Jan., pp. 2-4, figs. 5).—After a slight discussion of the subject, a special style is described in detail. This burette is filled from the bottom by a siphon from an overhead stock bottle using a three-way cock. The overflow runs into a small air chamber which in turn is connected by an ascending tube with the stock bottle.—E. B. HOLLAND.

BOTANY.

Transpiration into a saturated atmosphere, H. H. DIXON (*Proc. Roy. Irish Acad.*, 3. ser., 1 (1898), No. 5, pp. 627-635, figs. 2; *abs. in Bot. Gaz.*, 26 (1898), No. 2, p. 119).—The conclusions of the author, drawn from his experiments in saturated atmosphere, are as follows: The elevation of the water of the transpiration current when the leaves are surrounded by a saturated atmosphere is affected by pumping actions proceeding from the living cells of the leaves. Observations based on the drying back of branches furnished with dead leaves render it highly probable that the vital pumping actions of the leaves are partially or wholly responsible for the elevation of water even in an unsaturated atmosphere. These pumping actions are capable of raising water against an external hydrostatic pressure and in common with other vital actions they are accelerated by moderately high temperature and are dependent on the supply of oxygen. The cells adjoining the terminal portions of the water conduits appear to possess this activity, and in plants provided with water glands the pumping actions are not limited to the secreting tissue of these glands.

On the formation of proteids and the assimilation of nitrates by phænogams in the absence of light, U. SUZUKI (*Imp. Univ. Col. Agr. [Tokyo] Bul.*, Vol. 3, No. 5, pp. 488-507).—A number of experiments are reported with barley, *Phaseolus multiflorus*, and potato plants in which their ability to assimilate nitrogen and form proteid compounds in the dark was tested. The ability of these plants to assimilate nitrates in perfect darkness is affirmed, and it is stated that proteids can be formed from nitrates in perfect darkness when the conditions are favorable—that is, when sugar is present in the plant cells. When the available amount of sugar is insufficient, the reduction of nitrates and their assimilation does not take place. The intermediate product between nitrates and proteids is considered to be asparagin, and when the conditions of protein formation are imperfect this substance accumulates. The author concludes by commenting upon the investigations of a number of investigators on this subject.

The influence of gases and vapors upon the growth of plants, E. P. SANDSTEN (*Minnesota Bot. Studies*, 2. ser., 1898, No. 1, pp. 53-68).—A report is given upon a series of experiments conducted to test the influence of gases and vapors upon seeds and seedlings, growing shoots, resting bulbs, and upon plants growing in water cultures. The chemical materials used were alcohol, ammonia, carbon bisulphid, chloroform, ether, nitrous oxid, and oxygen. The various plants experimented upon were seeds and seedlings of maize, *Vicia faba*, and *Phaseolus multiflorus*. Dormant bulbs and corms of *Arisæma*, *Narcissus*, hyacinth, tulips, *Freesia*, and crocus. In the experiments with gases maize was grown in water cultures containing nutrient solutions. Duplicate experiments and controls were maintained for all the experiments and the results are tabulated.

From the tabulated material it appears that seeds of *Phaseolus* and *Vicia* will not germinate in an atmosphere containing 80 per cent of nitrous oxid. Seedlings of these plants will remain active for more than 24 hours in an atmosphere of commercial nitrous oxid, but no growth will take place. In some cases shoots exhibited accelerated growth after being kept in an atmosphere of free nitrous oxid, or where the amount of gas ranged from 25 to 100 per cent, but no growth could be detected during the experiments. Aquatic plants showed considerable increased growth in solutions saturated with nitrous oxid. Seeds germinated readily in atmospheres of free oxygen, but seedlings kept in such an atmosphere did not grow as rapidly as those in ordinary air. Growing shoots kept in an atmosphere containing 25 to 100 per cent of free oxygen remained unchanged for as long a period as 20 days, but upon removal slowly perished.

Vapors of ammonia when used in quantities not exceeding 1 to 24,000 are not harmful to the germination of seeds of *Phaseolus*. Seeds exposed for 9 days in glass chambers containing from 1 to 24,000 and 1 to 32,000 parts of ammonia germinated as freely as in the control experiments. On the other hand the seed of *Vicia faba* is very susceptible to the influence of this vapor, and specimens kept for 9 days in 1 to 28,000 of ammonia failed to germinate. Both the *Phaseolus* and *Vicia* seed kept for 9 days in an atmosphere containing 1 to 20,000 of ammonia failed to germinate. The growth of young seedlings of maize kept for 48 hours in a moist chamber containing 1 to 20,000 of ammonia was seriously retarded. Resting bulbs are not affected by being kept in atmospheres containing 1 part of ammonia in 5,000. Chloroform and ether have a very similar effect upon growth. Seedlings of maize kept in a moist chamber containing 1 to 10,000 parts of chloroform or ether showed a marked acceleration in growth after being removed from the moist chamber. An atmosphere containing 1 to 5,000 greatly retarded growth. Resting bulbs and growing shoots are equally susceptible and are killed after being exposed for 10 to 20 days in atmospheres containing 1 to 10,000 of either chloroform or ether. The carbon bisulphid in extremely small amounts proved injurious to all growing plants, although it was inoperative on resting seeds.

When used in quantities not exceeding 1 to 10,000, alcohol has no effect upon the growth of seedlings. If larger quantities are used the growth is retarded and the seedlings killed. Resting bulbs kept in an atmosphere containing 1 to 500 and 1 to 1,000 parts of alcohol grew, but the floral organs were dwarfed and the flower buds remained unopened.

The toxic action of a certain group of substances, R. H. TRUE (*Proc. Amer. Assoc. Adv. Sci.*, 47 (1898), p. 410).—The author states that common salt and potassium nitrate have long been regarded as essentially lacking in toxic action, and operate only through their osmotic activity. In his experiments cane sugar was assumed to be a purely

osmotic agent, and the concentration which a number of filaments of *Spirogyra* survived after an exposure of 24 hours was regarded as the measure of osmotic action which the alga can endure. This was found to be about 0.75 gm. molecules per liter.

Assuming the action of the other substances studied, which were glycerin, potassium nitrate, and common salt, to be purely osmotic, the concentrations calculated are glycerin, 0.75 gm. molecules per liter; common salt, 0.47 gm., and potassium nitrate 0.45 gm. molecules per liter. The limit of contraction for glycerin lies at a concentration greater than that of the cell sap and probably causes death by osmotic action. The limits of concentration for potassium nitrate and common salt lie much below the point of the same osmotic action as the cell sap and consequently they exert a pronounced toxic influence upon *Spirogyra*.

The acquisition of atmospheric nitrogen, W. M. MUNSON (*Maine Sta. Rpt. 1897, pp. 114-110*).—A résumé is given of the more important literature relating to this subject. The author briefly describes experiments conducted at the station on the practical application of soil inoculation. A quantity of soja beans were planted in drills and with the seed a number of tubercles from the previous year's crop at the Connecticut Storrs Station were scattered. The plants from inoculated soils were more stocky and of darker color than those in adjacent rows. Those plants growing in the inoculated soils bore an abundant supply of tubercles, while the others bore none. Inoculated plants were taller and produced more abundant pods per plant than in those grown in the uninoculated soil.

A limited trial of Nitragin for the common pea was made in which there was no appreciable effect from the use of the material. Tubercles developed abundantly on both lots, which was rather to be expected since peas had been freely grown in the vicinity for many years.

A bibliography of some of the more important papers to which the author's attention has been called is appended.

The second annual meeting of the Society for Plant Morphology and Physiology, E. F. SMITH (*Amer. Nat., 33 (1899), No. 387, pp. 199-217*).—Abstracts are given of the papers presented at the second meeting of this society at New York, December, 1898.

Notes on plants of the season, F. L. HARVEY (*Maine Sta. Rpt. 1897, pp. 179-184, pl. 1*).—Brief notes are given of a number of weeds, and attention called to the potato blight, strawberry-leaf blight, quince rust, and a blighting of maple leaves which was due to the dry hot wind following moist warm weather when the leaves were growing rapidly and in consequence quite tender. Notes are also given on 3 species of the stinkhorn fungi—*Phallus dæmommum*, *P. impudicus*, and *Mutinus brevis*.

On the number of rice shoots, I. INAGAKI (*Imp. Univ. Col. Agr. [Tokyo] Bul., Vol. 3, No. 5, pp. 415-420*).—The author has deduced a formula by which to ascertain the number of shoots to be expected from each grain in a given lot of seed, the variations due to variety, climate, soil, manure, cultivation, etc., being considered. When tested on about a dozen varieties of rice grown under varying conditions, the greatest variation observed was 2.7 per cent, the calculated number being that much too great.

The dichotomous group of *Panicum* in the Eastern United States, W. W. ASHE (*Jour. Elisha Mitchell Sci. Soc.*, 15 (1898), No. 1, pp. 22-62).—The author comments on the confusion in this group, rearranges the species, and describes about 20 new species.

Studies in Cyperaceæ, T. HOLM (*Amer. Jour. Sci.*, 4. ser., 7 (1899), No. 3, pp. 171-183, figs. 5).—Notes are given on *Lipocarpa maculata*, *L. argentea*, *L. sphaecelata*, and *L. microcephala*.

A memoir on the Chlamydomonadineæ, P. A. DANGEARD (*Botaniste*, 6. ser., 1899, Nos. 2-6, pp. 65-299).

Contributions to the history of the india-rubber plant, E. GOEZE (*Wiener Illus. Gart. Ztg.*, 23 (1899), No. 1, pp. 15-24).

The occurrence of copper in the plant world, G. B. FRANKFORTER (*Chem. News*, 79 (1899), No. 2044, pp. 44, 45).

Concerning the constituents of the seed of *Pinus cembra*, E. SCHULZE and N. RONGGER (*Landw. Vers. Stat.*, 51 (1898), No. 2-3, pp. 189-204).

The constituents of the seed of *Picea excelsa* and its proteids, N. RONGGER (*Landw. Vers. Stat.*, 51 (1898), No. 2-3, pp. 89-116).

The physiological action of certain plasmolyzing agents, R. H. TRUE (*Bot. Gaz.*, 26 (1898), No. 2, pp. 407-416).—The author reports upon the physiological action on *Spirogyra* of various concentrations of cane sugar, glycerin, sodium chlorid, and potassium nitrate.

The effect of the electric current on plants, B. KLEIN (*Ber. Dent. Bot. Gesell.*, 16 (1898), No. 10, pp. 335-346).—The stimulating effect of electric currents on a number of leaves and seedlings is shown.

On the effects of stimulative and anesthetic gases on transpiration, H. DIXON (*Proc. Roy. Irish Acad.*, 3. ser., 4 (1898), No. 5, pp. 618-626, fig. 1).

The primary synthesis of proteids in plants, W. M. KOZLOWSKI (*Bul. Torrey Bot. Club*, 26 (1899), No. 2, pp. 35-57).—The author reviews the various hypotheses relative to the formation of proteids in plants, and states his own theory of their formation from lower nitrogenous combinations.

Formation of albumen in the generation of onion bulbs, W. ZALESKI (*Ber. Dent. Bot. Gesell.*, 16 (1898), pp. 147-151; *abs. in Jour. Roy. Micros. Soc.* [London], 1899, No. 1, p. 56).—The author has determined a considerable increase in the proteid substance of bulbs of *Allium cepa* germinated in the dark, the percentage rising from 32 to as much as 52.5. The bulbs are said to contain a much smaller proportion of reserve proteids than the seeds. The amount of asparagin remains about constant, and the formation of proteids in the dark can not be said to be due exclusively to asparagin and glutenin.

Investigations on the sex organs and fruiting of *Cycas revoluta*, S. IKENO (*Jour. Col. Sci. Imp. Univ. Tokyo*, 12 (1898), No. 3, pp. 151-214, pls. 8).

Studies on the fecundation and embryology of *Ginkgo biloba*, S. HIRASÉ (*Jour. Col. Sci. Imp. Univ. Tokyo*, 12 (1898), No. 2, pp. 103-149, pls. 3).

Dimorphism in Australian cruciferous plants, R. TATE (*Trans. Roy. Soc. South Australia*, 22 (1898), No. 2, pp. 122-124).

The root tubercles of alders and the Eleagnaceæ, L. HILTNER (*Forstl. Naturw. Ztschr.*, 7 (1898), No. 12, pp. 415-423).—Notes are given on the tubercles on the roots of *Alnus*, *Shepherdia*, *Hippophaë*, etc., of the organism causing the swellings, their entrance through the root hairs, and their ability to assimilate atmospheric nitrogen.

Inoculation for leguminous plants, SALFELD (*Dent. Landw. Presse*, 26 (1899), No. 13, pp. 120-121).—A rather popular article on the object and results of soil inoculation for nitrogen assimilation.

Experiments with Alinit: An answer, GERLACH (*Fühling's Landw. Ztg.*, 48 (1899), No. 2, pp. 69, 70).—This is a reply to an article on experiments with Alinit by Stoklasa, which immediately precedes it. The author cautions the farmers against the use of Alinit until it has been carefully and scientifically tested.

The use of Alinit in the culture of cereals, L. MALPEAUX (*Ann. Agron.*, 24 (1898), No. 10, pp. 482-492; *abs. in Chem. Ztg.*, 22 (1898), No. 36, *Repert.*, p. 313).—Upon poor

sandy soils Alinit was without effect in increasing the harvest of cereals. Where humus compounds were abundant Alinit did increase the crop, but inoculations in ordinary or poor soils were without appreciable influence.

General methods in botanical microtechnique, J. H. SCHAFFNER (*Jour. Appl. Micros.*, 2 (1899), No. 1, pp. 225-227).—This article treats of the preparation of botanical material for paraffin embedding.

Several crosses of spelt and wheat, P. H. STOLL (*Deut. Landw. Presse*, 26 (1899), No. 1, p. 3; 4, p. 29; 8, p. 65; 11, p. 95, figs. 7).—Crosses obtained by fertilizing Square Head wheat with pollen of Brown Winter spelt are described and illustrated.

Results of experiments in the cross breeding of cereals and peas, W. SAUNDERS (*Canada Expt. Farms Rpt. 1897*, pp. 67-69).—Notes on the work of cross breeding spring wheat, barley, oats, peas, and of wheat with rye at the Central Experimental Farm.

The king-devil weed, F. L. HARVEY (*Maine Sta. Rpt. 1897*, pp. 185-191, pl. 1).—Notes are given on the history and distribution of *Hieracium proaltum*. This weed is reported as a rather serious pest in 5 or 6 different localities in the State, and remedies are suggested for the possible destruction and prevention of the spread of this plant, which would in all probability prove a serious weed pest.

METEOROLOGY—CLIMATOLOGY.

Meteorological observations (*Massachusetts Hatch Sta. Met. Buls.* 118, 119, 120, pp. 4 each).—The usual summaries of observations and notes on the weather during October, November, and December, 1898. In addition, No. 120 gives an annual summary for 1898, the principal data in which are as follows:

*Pressure*¹ (inches).—Maximum, 30.76, March 26; minimum, 29.01, February 16; mean, 30.008. *Air temperature*² (degrees F.).—Maximum, 96.5, July 3; minimum, -19, February 3; mean, 47.5; mean sensible (wet bulb), 15.2; annual range, 115.5; maximum daily range, 40, February 3; minimum daily range, 2.5, April 5; mean daily range, 20.3. *Humidity*.—Mean dew point, 41.6; mean force of vapor, 0.426; mean relative humidity, 79.8. *Precipitation*.—Total rainfall or melted snow, 54.25 in.; number of days on which 0.01 in. or more rain or melted snow fell, 135; total snowfall, 69.5 in. *Weather*.—Mean cloudiness observed, 60 per cent; total cloudiness recorded by sun thermometer, 2,317 hours, or 52 per cent; number of clear days, 78; number of fair days, 138; number of cloudy days, 149. *Wind*.—Prevailing direction, W. or S. 86° W.; total movement, 48,425 miles; maximum daily movement, 675 miles, November 27; minimum daily movement, 4 miles, January 18; mean daily movement, 133 miles; mean hourly velocity, 5.5 miles; maximum pressure per square foot, 30.5 miles, 78 miles per hour, September 7. *Dates of frosts*.—Last, April 27; first, September 21. *Dates of snow*.—Last, April 6; first, November 24.

Meteorological observations (*Maine Sta. Rpt. 1897*, pp. 201, 202).—This is a monthly summary of observations during 1897 on atmospheric pressure, temperature, precipitation, cloudiness, and wind movement. The mean pressure for the year was 29.84 in.; the mean temperature, 42.46°, the mean for 29 years being 42.34°; precipitation, 39.99 in. (average for 29 years 45.2); snowfall, 58 in. (mean for 29 years 92.4); number of clear days, 125; number of cloudy days, 137.

Meteorological observations, W. T. ELLIS ET AL (*Canada Expt. Farms Rpt. 1897*, pp. 60, 273, 356, 357, 434).—Brief summaries of observations and general notes on the weather at the Central Experimental Farm and the experimental farms for the Maritime Provinces, Manitoba, the Northwest Territories, and British Columbia.

¹ Reduced to freezing and sea level. The instruments are 2,735 ft. above sea level,

² Temperature in ground shelter 51 ft. below level of other instruments.

Report of the Chief of the Weather Bureau for 1898, W. L. MOORE (*U. S. Dept. Agr., Weather Bureau Doc. 181*, pp. 30).—This is a summary account of the operations of the Weather Bureau during the fiscal year ending June 30, 1898, with an appendix by L. B. GARRIOTT on the storms, cold waves, and floods of the year.

Monthly bulletins of the River and Flood Service, E. B. GARRIOTT (*U. S. Dept. Agr., Weather Bureau Doc. 173*, pp. 13, chart 1; 175, pp. 15, chart 1; 177, pp. 15, chart 1).—These bulletins give the usual summaries of observations on river stages and the condition of navigation during the months of July, August, and September.

The probable state of the sky along the path of total eclipse of the sun, May 28, 1900, F. H. BIGELOW (*U. S. Dept. Agr., Weather Bureau Doc. 179*, pp. 6, chart 1).—This is a second report¹ from observations made in 1898, reprinted from *Monthly Weather Review*, 26 (1898), No. 9, p. 404.

Phenological investigations in Schleswig-Holstein in 1897, P. KNUTH (*Schr. Naturw. Ver. Schleswig-Holstein*, 11 (1898), No. 2, pp. 252-259).

The influence of land and sea winds on the nitrogen content of rain, L. ANDERLAND (*Landw. Vers. Stat.*, 59 (1898), No. 1-2, pp. 159, 169).—This is a brief review of a report of observations made at Tuy in Galicia (Spain), showing that rains brought by winds from the ocean contain less ammonia than those coming from the direction of the land. The author urges stations favorably located for such work to make further observations on this point and also on the influence of manufacturing industries upon the nitrogen content of rain.

Climatology in Belgium, F. DE COURNELLES (*Jour. Hyg.*, 23 (1898), No. 1153, pp. 505-508).

The cyclone at Swabia, July 14, 1894, F. HORN (*Forstl. Naturw. Ztschr.*, 7 (1898), No. 12, pp. 429-438, figs. 4).—A discussion of the causes and characteristics of this storm.

Cultural conditions of Tunis, DYBOWSKI (*Compt. Rend. Acad. Sci. Paris*, 128 (1899), No. 2, pp. 133-135; *Rev. Sci. [Paris]*, 4, ser., 11 (1899), No. 3, p. 85).—A discussion of the climatic conditions in this country, confined largely to the amount and distribution of rainfall.

Aneroid barometers, C. F. MARVIN (*U. S. Dept. Agr., Weather Bureau Doc. 180*, pp. 6).—The unreliability of aneroid barometers and the results of experiments on such barometers by C. Chree at Kew² observatory are briefly discussed.³

WATER—SOILS.

Analysis of Malmesbury soils, O. F. JURITZ (*Agr. Jour. Cape of Good Hope*, 13 (1898), No. 13, pp. 818-822).—In the Malmesbury district and in other portions of South Africa, there are soil areas which contain numerous slight elevations, from 1 to 4 ft. in height and 20 or more yards in diameter. The soil on these hillocks is alleged to be extremely rich, and cereals of all kinds are said to grow on them with luxuriance, while on the lower ground between the elevations the soil is poor and produces scanty crops. Analyses of samples of soil from

¹For first report see U. S. Dept. Agr., Weather Bureau Doc. 112; *Monthly Weather Review*, 25 (1897), No. 9, p. 394.

²Report from Observatorio meteorológico del colegio de la compañía de Jesús en Guardia. Tuy, 1894, pp. 62.

³Phil. Trans. Roy. Soc. [London], ser. A, 195 (1895).

⁴See also U. S. Dept. Agr., Weather Bureau, *Monthly Weather Review*, 26 (1898), No. 9, p. 410.

these hillocks and from the adjacent level land gave the following average results:

Composition of hillock and level soil in South Africa.

	Lime.	Potash.	Phosphoric acid.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Hillock soil	0.078	0.075	0.051
Level soil019	.061	.032

It will be seen from the table that each of the three constituents is less abundant in the level soil than in the hillock soil, the lime being especially deficient.

Canadian soils, F. T. SHUTT (*Canada Expt. Farms Rpt. 1897, pp. 151-170*).—The results are presented of chemical and partial mechanical analyses (1) of soils sent by farmers for examination, including 2 samples from British Columbia, 5 (1 of muck soil) from Ontario, and 4 from Quebec; and (2) of virgin soils,¹ including 29 samples (with sub-soils) from British Columbia, 8 from the Northwest Territories and Manitoba, 9 from Ontario, 10 from Quebec, and 5 from the Maritime Provinces—New Brunswick, Nova Scotia, and Prince Edward Island. The samples and the regions from which they were obtained are briefly described, and the value of soil analysis, standards of fertility, and methods of analysis are discussed.

“The solvent used in the determination of total or maximum percentages of the mineral constituents has been hydrochloric acid, sp. gr. 1.115 (corresponding to 22.86 per cent HCl), 10 gm. of the air-dried soil being digested with 100 cc. of the acid at the temperature of the water bath for 10 hours.

“For the estimation of the available potash and phosphoric acid 1 per cent citric acid solution has been employed, digesting 100 gm. of air-dried soil with 500 cc. of the solvent for 5 hours at room temperature.”

The latter determinations were made in 1 soil only. The average composition of the surface soils examined is given in the following table:

Average analyses of virgin surface soils of Canada.

Number of samples.	Province.	Potash.	Phosphoric acid.	Nitrogen.	Lime.
		<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
21	British Columbia	0.42	0.27	0.262	1.17
7	Northwest Territories and Manitoba44	.19	.537	1.08
6	Ontario (Muskoka only)22	.15	.135	.44
6	Quebec44	.20	.226	.52
5	Maritime Provinces44	.11	.130	.11
45	Average of all39	.18	.258	.66

Although the above are averages of analyses of samples which “are typical, and, as far as possible, thoroughly representative of large areas,

¹For previous work on such soils see Canada Expt. Farms Rpt. 1896, p. 184 (E. S. R., 9, p. 821).

taken from the thousands of square miles of uncultivated soil in the Dominion, they do not afford sufficient basis for generalizations regarding the average soil fertility of the yet untilled areas of the respective provinces."

"Our data indicate that good agricultural soils in Canada possess usually between 0.25 per cent and 0.5 per cent potash; less than 0.15 per cent in our experience, points to the necessity, or at all events to the value of potassic fertilizers, though with good climatic and soil conditions the limit might be reduced to that suggested by Hilgard.

"The phosphoric acid in Canadian virgin soils of average fertility lies usually between 0.15 and 0.25 per cent. Some good soils contain from 0.25 to 0.3 per cent, and a few exceed the latter figure. The adequacy or otherwise of phosphoric acid in a soil would appear to depend largely on the accompanying amount of lime. Increased crop production has usually followed the application of phosphatic fertilizers to soils containing less than 0.15 per cent phosphoric acid.

"Lime ranks next in importance to potash and phosphoric acid in a consideration of the mineral constituents of plant food. Our experience goes to show that clay soils, containing less than 0.5 per cent will have their productiveness increased by a dressing of lime in one or other of its agricultural forms. Peaty soils and soils generally that are rich in organic matter, are frequently poor in this element. All such have been found to respond to an application of lime, and more particularly so when given in conjunction with potash and phosphoric acid. For these classes of soils, therefore, I deem it advantageous that they should contain at least 1 per cent of lime.

"Richness in nitrogen may be measured to a large degree by the organic or humus content, though the condition or stage of decomposition of this organic matter is an important factor in determining the nitrogen's availability. The larger number of our good soils contain between 0.1 and 0.2 per cent, though many reach 0.5 per cent and some exceed 1 per cent nitrogen."

Some investigations on the nitrogenous matter of the soil, A. PAGNOUL (*Ann. Sci. Agron.*, 1898, II, No. 1, pp. 97-112).—Previous work by the author is briefly summarized, and an account is given of 6 series of pot experiments carried out during 1897. The general plan of these experiments was as follows: Nitrogen in 3 forms—nitric, nitrous, and ammoniacal—was determined in the soil at the beginning of the experiment (200 gm. lots being used), various nitrogenous materials were added, and at intervals during periods of from 80 to 118 days determinations of nitrogen in the above forms were again made.

In the first series a comparison was made between the changes which the organic nitrogen of the soil and that introduced in the form of dried blood and manure undergoes. In these experiments 7.4 per cent of the original nitrogen in the soil, 59 per cent of the nitrogen of the dried blood, and 48 per cent of the nitrogen of the manure was rendered soluble in 80 days, due principally to nitrification. Over 50 per cent of the nitrogen of the dried blood became soluble in 12 days.

In the second series of experiments the assimilability of nitrogen in ground meat, peanut cake, and sesame cake was compared. Sixty-two per cent of the nitrogen in the meat powder was rendered soluble in 13 days, 100 per cent in 116 days; 64 per cent of the nitrogen of the peanut cake became soluble in 13 days, 100 per cent in 116 days; and 62

per cent of the nitrogen of the sesame cake was rendered soluble in 13 days, 94 per cent in 116 days.

In the third series of experiments castor-bean cake, colza cake, and wool waste (dust) were compared. In case of the first 52 per cent of the nitrogen was rendered soluble in 11 days, 80 per cent in 107 days; in the second case 32 and 70 per cent, respectively; and in the third case 6 and 46 per cent, respectively.

In the fourth series of experiments the effect of previously heating the soil to 100° and adding a small amount of sulphuric acid was tested. In this series 2 pots received dried blood without previous treatment of the soil, 1 received dried blood after the soil had been heated to 100°, and another received dried blood after heating to 100° and adding a small amount of acid. The heating had the effect of reducing the nitric nitrogen and increasing the amount of ammoniacal and nitrous nitrogen produced. Heating to 100° C., especially with the addition of acid, appears to have been destructive to the nitrifying organisms.

In the fifth series of experiments an investigation was made of the progress of nitrification in soils to which mixtures of horse manure and nitrate of potash or sulphate of ammonia with or without starch were added. The results indicate that horse manure, especially in the presence of starch, tends to cause the disappearance of nitrates, but under the conditions of these experiments, *i. e.*, with a temperature of 30° and a sufficient supply of air and moisture, this disappearance of nitrogen is not due to an evolution of free nitrogen but largely to the formation of new organic compounds of nitrogen.

In the sixth series of experiments a comparison was made of the transformations of nitrogen which go on in soil very rich in humus and nitrogen, with and without the addition of nitric and ammoniacal nitrogen. The transformations of nitrogen were somewhat slower in this case than in the case of an ordinary soil.

On the composition of natural humus substances, G. ANDRÉ (*Compt. Rend. Acad. Sci. Paris*, 127 (1898), No. 11, pp. 411-417; *abs. in Ann. Agron.*, 24 (1898), No. 12, pp. 602-604).—In the investigations here reported vegetable mold, moor soil, compost, and peat were treated with (1) potash followed by hydrochloric acid and (2) hydrochloric acid followed by potash. The ammonia volatilized and the nitrogen soluble and insoluble in the acid and alkali were determined. The results reported show the complex character of the nitrogenous matter of the soil. Previous work by Berthelot and André¹ led to the conclusion that the nitrogenous matter of the soil is of an amid character.

The lime content of soils and nitrification, F. POLZENIUSZ (*Ztschr. Landw. Versuchs. Oesterr.*, 1 (1898), p. 235; *abs. in Centbl. Agr. Chem.*, 28 (1899), No. 1, pp. 12, 13).—Samples of 200 gm. each of a soil containing 0.546 per cent of lime, 0.014 per cent of which was carbonate, were placed in glass dishes, and in different cases 0.0866 gm. of nitrogen in

¹ *Ann. Chim. et Phys.*, 6, ser., 11 (1887), p. 368; 25 (1892), p. 314.

the form of bone meal and of sulphate of ammonia were added. In one series of experiments no lime was added; in the other series 3 gm. carbonate of lime were added in each case. The soils were kept moist, and the carbon dioxide which passed off was measured. After several weeks the samples were extracted with water, and ammonia and nitric nitrogen were determined in the solution. The soils were also extracted with dilute hydrochloric acid and the ammonia determined. The results show that the soil originally contained sufficient lime for the nitrification of the bone-meal nitrogen, but that the addition of lime was necessary for the transformation of the ammonium sulphate. In case of the soil to which no lime was added only 0.19 per cent of the nitrogen added in form of ammonium sulphate was nitrified, while in the experiments with lime 76 per cent of this nitrogen was transformed. The author concludes that the good results obtained in this case are due to the neutralization of the sulphuric acid of the sulphate of ammonia by the calcium carbonate, and that this result can not be accomplished as effectively by any other form of lime.

The effect of carbon bisulphid on the fertility of soils, E. WOLLNY (*Vrtljschr. Bayer. Landw. Rath.*, 1898, No. 3, pp. 319-312).—The results of a series of experiments are recorded in which the effect of carbon bisulphid on the fertility of the soil was studied. Pot and plat experiments were made with various crops and fertilizers and the carbon bisulphid was applied at different times. The author concludes that treating the soil with carbon bisulphid during the vegetative period of the crop is detrimental to the plants, but if the soil is treated several months before the crop is planted its fertility is increased to a noticeable degree, and the effect is noticeable in the growth of several succeeding crops. An explanation of this action of the carbon bisulphid on the fertility of the soil is not given. It was found that activity of the nitrifying organisms and the root-nodule bacteria of legumes is temporarily retarded by the carbon bisulphid treatment, but that eventually their activity again becomes normal.

Well water from farm homesteads, F. T. SHUTT (*Canada Expt. Farms Rpt.* 1897, pp. 180-185).—The results are given of analyses with reference to sanitary condition of 66 samples of well water; "one from British Columbia, 6 from the Northwest Territories, 28 from Ontario, 8 from Quebec, 7 from New Brunswick, and 17 from Prince Edward Island. Of these, 50 per cent were reported dangerously polluted and unsafe for drinking purposes, 25 per cent as suspicious and in all probability as unsafe, and 25 per cent as unpolluted and wholesome."

Soil analysis, its historical development and its significance to agriculture, A. OTTO (*Fühling's Landw. Ztg.*, 47 (1898), No. 23, p. 892).—A general discussion.

The calcareous efflorescence found on cultivated soils, F. SESTINI (*Atti. R. Accad. Econ. Agr. Georg. Firenze*, 21 (1898), No. 2, pp. 14, pl. 1).—The analyses showed the samples of this substance examined to be essentially carbonate of calcium and magnesium with a small amount of carbonate of ammonia.

The judging of the physical properties of soils by means of the heat which they evolve when moistened, A. MITSCHERLICH (*Beurtheilung der physikalischen Eigenschaften des Ackerbodens mit Hilfe seiner Benetzungswärmer. Inaug. Diss., Kiel*, 1898, pp. 52, pls. 2).—See E. S. R., 10, p. 123.

On the influence of frost on cultivated soils, E. WOLLNY (*Fühling's Landw. Ztg.*, 47 (1898), No. 17, pp. 641-650; 18, pp. 675-681; 19, pp. 709-714; 20, pp. 749-756).—A general discussion of this subject based largely upon the author's extended studies.

Is a lack of lime general in Rhode Island soils? H. J. WHEELER and G. E. ADAMS (*Rhode Island Sta. Bul.* 49, pp. 37-48).—This is a brief summary of experiments with lime during a number of years on a variety of crops and at different points in Rhode Island. The results indicate the wide distribution in the State of soils which are benefited by applications of lime. It was found that beets "furnish an unusually good crop for testing soils as to their lime requirements."

Comparative trials of lime worked into the soil before seeding and applied as a top-dressing afterwards, H. J. WHEELER and J. A. TILLINGHAST (*Rhode Island Sta. Bul.* 49, pp. 48-50).—From the results of experiments made at the station on timothy "it seems that the recommendation to lime land before seeding is one that should be adhered to if the best results are to be obtained."

FERTILIZERS.

The fertilizing value of street sweepings, E. E. EWELL (*U. S. Dept. Agr., Division of Chemistry Bul.* 55, pp. 19).—This bulletin summarizes data regarding disposal of street sweepings in 204 out of the 354 cities and towns of the United States having 10,000 or more inhabitants, as furnished by replies to circulars of inquiry sent to officials in charge of street-cleaning departments. "The total quantity of street sweepings annually collected may be estimated at not far from 3,000,000 tons. . . . In general terms it may be stated that the cities representing one-fourth of the urban population of the country make an effort to utilize the fertilizing value of some portion of their street sweepings."

Analyses of 18 samples of sweepings collected in Washington, D. C., are reported. In these the nitrogen varied from 0.17 to 1.18 per cent, phosphoric acid from 0.01 to 0.16 per cent, and potash from 0.09 to 0.5 per cent. Extracts from letters from farmers and gardeners who have used street sweepings are quoted to show "that well-selected and judiciously used street sweepings possess considerable manurial value."

Valuing nitrogen at 10 cts. per pound and disregarding phosphoric acid and potash, the poorest sample of sweepings examined would be worth 34 cts. per ton; the richest, \$1.46.

Contribution to the study of street dust as a fertilizer, A. CASALI (*Contributo allo studio pratico della polvere di strada come materia ammendante e concimante*, Bologna, Società Tipografica già Compositori, 1899, pp. 23; *Staz. Sper. Agr. Ital.*, 31 (1898), pp. 377-396; *abs. in Chem. Centbl.*, 1898, II, No. 22, p. 1106).—This article discusses the formation, composition, properties, fermentation, and uses of street dust, and reports results of analyses of a few samples. The composition of the substance examined was as follows: Moisture 1.20, nitrogen 0.05 (traces in form of ammonia and nitric acid), potash 0.16, lime 22.34, phosphoric acid 0.09, carbon dioxide 17.33, and silica 46.44 per cent. Of the material, 15.9 per cent was soluble in 5 per cent acetic acid, 30 per cent in 25 per cent hydrochloric acid, and 0.4 per cent in boiling water. It lost 33.5 per cent on calcination.

The author concludes from his study that one of the most marked and important properties of this material is its power of inducing beneficial fermentations in manure and in the soil.

Seaweed as manure, J. HENDRICK (*Agr. Students' Gaz.*, n. ser., 9 (1898), No. 2, pp. 41-49).—The author reports analyses and discusses the fertilizing value of 3 samples of cut weed, or shore weed, including 2 of *Fucus nodosus* and 1 of *F. vesiculosus*: 1 sample of *F. ceranoides*, which grows in brackish or almost fresh water, and 3 samples of drift weed, including 1 of mixed seaweed, 2 of *Laminaria digitata* (stalk and blade), 1 of *L. saccharina*, and 1 of *Alaria esculenta*. The author concludes that, weight for weight, seaweed is about equal in value to barnyard manure, but differs from the latter in its higher content of potash and lower content of phosphoric acid. It is also claimed that seaweed must undergo decay before its nitrogen (rarely less than 0.5 per cent) is available for plants or even ready for nitrification. The potash in seaweed is in a very available form. If fresh living seaweed is placed in fresh water "a large part of its potash will diffuse out into the water as soluble potash salts, chiefly chlorid, in a few hours."

The black phosphates of the Pyrenees, D. LEVAT (*Compt. Rend. Acad. Sci. Paris*, 127 (1898), No. 21, pp. 834-836; *abs. in Rev. Sci. [Paris]*, 4. ser., 10 (1898), No. 23, p. 736).—Extensive deposits of a phosphate having the appearance of anthracite have recently been discovered in the Pyrenees. This deposit lies between strata of marble or limestone and schist. The richer portion of the deposit contains numerous hard brilliant black nodules which contain from 65 to 75 per cent of tricalcium phosphate. The gangue surrounding the nodules is also phosphatic. The phosphate contains a considerable amount of organic matter yielding from 3 to 5 kg. of organic nitrogen per ton. The bed is from 8 to 10 meters thick.

Report of analyses of commercial fertilizers for the spring of 1898, L. L. VAN SLYKE (*New York State Sta. Bul.* 115, pp. 49-119).—This bulletin contains notes on the valuation of fertilizers, suggestions regarding purchase of fertilizing materials, a list of manufacturers complying with the requirements of the State fertilizer law, an explanation of terms used in stating results of analyses, and tabulated analyses of 1,183 samples of commercial fertilizers, representing 739 different brands collected by the station during the spring of 1898. Of the 739 brands examined 578 were complete fertilizers. "Of the others 55 contained phosphoric acid and potash without nitrogen, 47 contained nitrogen and phosphoric acid without potash, 8 contained nitrogen only, 44 contained phosphoric acid alone, and 7 contained potash salts only." In the complete fertilizers the nitrogen varied from 0.12 to 8.21 per cent, averaging 2.2 per cent. The available phosphoric acid varied from 3.69 to 14.28 per cent, averaging 8.65 per cent. The potash varied from 0.22 to 15.22 per cent, averaging 4.91 per cent. The average amounts of nitrogen, available phosphoric acid, and potash exceeded the guaranteed average by 0.14, 1. and 0.24 per cent, respectively.

In 110 cases the potash in the complete fertilizers was in the form of sulphate free from an excess of chlorids.

"The retail selling price of the complete fertilizers varied from \$15 to \$45 a ton and averaged \$27.65. The retail cost of the separate ingredients unmixed averaged \$18.52 or \$9.13 less than the selling price."

On the occurrence of perchlorate in nitrate of soda and its injurious effect upon the growth of cereals and sugar beets, A. ZAHARIA (*Bul. Soc. Sci. Bucharest, 7, pp. 361-407; abs. in Chem. Centbl., 1898, II, No. 22, p. 1106*).—The author gives a very complete review of the literature of this subject and reports the results of 3 series of his own experiments on the action of perchlorate on the germination and growth of the more important agricultural plants. Experiments were conducted both in the field and in vegetation pots.

As a rule the germinative power of cereals sustained little or no injury from the perchlorate, although in case of barley and oats treated with concentrated solutions the development of the plantlet was retarded. In case of beet seed, on the other hand, neither the germinative power nor the growth of the plantlet was seriously interfered with by the perchlorate solutions. It was found in general that nitrate of soda containing 1.5 per cent of perchlorate had no injurious effect upon wheat and barley. Small amounts of perchlorate were apparently beneficial to beets. The growth of peas was retarded and the yield decreased by perchlorate.

Egyptian clay and salt, J. GOLDING (*Rpt. on Experiments, Agr. Dept. Univ. College, Nottingham, 1898, pp. 4*).—A brief account is given of experiments on permanent meadow, barley, oats, and wheat with a crude salt obtained by lixiviation of the nitrate-bearing clays which occur in upper Egypt (E. S. R., 6, p. 516). The sample of salt used in these experiments contained about 56 per cent of sodium nitrate, 31 per cent sodium chlorid, and 9.5 per cent of sodium sulphate. The results of the experiments indicate that the salt is "worth quite as much per unit of nitrogen as nitrate of soda imported from Chile, also that dressings of 1½ cwt. per acre are likely to produce good results, especially on barley and pasture grass."

On the fertilizing value of the nitrogen of fresh and old barnyard manure, M. MAERCKER (*Agr. Chem. Vers. Stat. Halle, 2 (1898), p. 51*).

On green manuring, RÜMKER (*Ueber Gründüngung. Schönberg-Berlin: F. Telge, 1898, pp. 48*).—This little pamphlet discusses the general principles of green manuring and their application in the management of light and heavy soils. A brief bibliography of the subject is appended.

Notes upon garbage fertilizers, W. FREAR (*Pennsylvania Dept. Agr. Rpt. 1897, pp. 524-529*).—Analyses of crematory ashes and garbage tankage, alone or mixed with phosphates and sulphuric acid, are reported, and the fertilizing value of these substances is discussed.

Fertilizers in the village, H. FAYET (*Les engrais au village. Paris: Librairie Larousse, 4. ed., pp. 8+200*).—An elementary general treatise on fertilizers, designed for small farmers in France.

Naturally-occurring fertilizers, F. T. SHUTT (*Canada Expt. Farms Rpt. 1897, pp. 170-179*).—Analyses, with notes on use as fertilizers, of 9 samples of swamp muck; 6

samples of marsh, creek, and tidal deposits; 1 sample of marl; 2 samples of lobster refuse (bodies and tails); 1 of limekiln ashes; 1 of purslane; 1 of a fraudulent mixture "for making manure," and 2 of moss litter.

On the fertilizing value of olive cake (*L'Engrais*, 11 (1899), No. 7, p. 159).—Analyses are given which show 0.75 to 0.77 per cent of nitrogen, 0.17 to 0.20 per cent of phosphoric acid, and 0.43 to 0.45 per cent of potash.

Inspections for 1897, C. D. WOODS (*Maine Sta. Rpt.* 1897, pp. 51-60).—This is a brief summary of the work done during the year in the inspection of fertilizers and feeding stuffs, with brief reference to the testing of seeds and of chemical glassware used in creameries.

The fertilizer law of South Australia, W. L. SUMMERS (*Jour. Agr. and Ind., South Australia*, 2 (1899), No. 6, pp. 499, 500).—An abstract.

Tabulated analyses of commercial fertilizers, T. J. EDGE and W. FREAR (*Pennsylvania Dept. Agr. Rpt.* 1897, pp. 797-836).—A reprint of Bul. 33, Pennsylvania Dept. Agr. (E. S. R., 9, pp. 825).

Fertilizer experiments with steamed bone meal, B. SCHULZE (*Jahrb. Agr. Chem. Vers. Staf. Breslau*, 1896; *abs. in Centbl. Agr. Chem.*, 28 (1899), No. 2, pp. 81-85).—From the results of experiments with winter wheat, potatoes, and sugar beets on loamy and clayey soils rich in humus the author concludes that bone meal is about as effective as superphosphate.

Is intensive manuring profitable at present prices for crops? P. WAGNER (*Ztsch. Landw. Ver. Hessen*, 1898, No. 11, p. 135; *abs. in Centbl. Agr. Chem.*, 28 (1899), No. 3, pp. 85-89).—The results of numerous experiments are cited to show that under the conditions of these experiments this question should be answered in the affirmative.

FIELD CROPS.

Experiments with field crops, W. SAUNDERS (*Canada Expt. Farms Rpt.* 1897, pp. 5-60, fig. 1, pls. 2).—The experiments in 1897 consisted of variety, fertilizer, and culture tests with field and forage crops. The results of vitality tests of grain and other seeds, and the amount of seed distributed in 1897 are reported in tables. The average results of the variety tests obtained on all the experimental farms has been previously reported (E. S. R., 9, p. 826).

Experiments were begun to ascertain the value of rolling and harrowing land sown with clover, and of sowing different quantities of clover per acre with barley. Harrowing only after sowing without rolling gave the best yield. However, the plat not rolled or harrowed after sowing yielded but 1 bu. per acre less. The experiments showed that clover can be grown with grain without lessening the yield. About 10 lbs. of clover seed per acre was used in most cases. The largest weight of clover leaves, stems, and roots, 8 tons 505 lbs. per acre, was produced on 2 plats, one sown with oats and 10 lbs. of mammoth red clover per acre, and the other with barley and 10 lbs. of common red clover per acre. The weight was determined on October 20.

Horse beans, soy beans, sunflowers, buckwheat, flax, and awnless brome grass were grown experimentally. Short notes on each crop and the yields produced are given. The results of fertilizer experiments carried on for a number of years with 19 applications of various fertilizers, used singly and in different combinations, are reported in tables. The crops grown in connection with these tests were wheat, barley,

oats, corn, mangel-wurzels, turnips, and potatoes. In general, the application of 15 tons of fresh barnyard manure per acre gave the best results.

Farm crops at the experimental farm at Brandon, Manitoba. S. A. BEDFORD (*Canada Expt. Farms Rpt. 1897, pp. 307-328*).—The experiments reported included variety tests of wheat, oats, barley, peas, corn, turnips, mangel-wurzels, carrots, sugar beets, potatoes, millets, clovers, and grasses, and trials of early, medium, and late sowings of wheat, oats, barley, and peas. All results are given in tables.

Wheat, after a summer fallow, produced a better yield and heavier grain than wheat grown on spring-plowed or fall-plowed land. A test of preparing unplowed stubble land for wheat showed that disking the land after burning the stubble and then drilling in the seed gave better results than drilling the seed on burned or unburned stubble, or on disked unburned stubble land. Very smutty Red Fife wheat treated with a bluestone solution at the rate of 1 lb. bluestone to 10 bu. of wheat yielded 20 bu. 10 lbs. per acre, the grain weighing 59 lbs. per bushel, and the same seed sown untreated yielded 8 bu. 40 lbs. per acre, the grain weighing 46 lbs. per bushel.

Among the 10 grasses tested western rye grass (*Agropyrum tenerum*) and awnless brome grass (*Bromus inermis*) were the most productive. In most cases sowing the seed at the rate of 15 lbs. per acre gave the best results.

Farm crops at the experimental farm at Indian Head, Northwest Territories, A. MACKAY (*Canada Expt. Farms Rpt. 1897, pp. 357-379*).—Variety tests were made with spring wheat, barley, oats, peas, corn, millets, grasses, root crops, and potatoes. Tests of early, medium, and late sowings and of sowing different quantities of seed per acre are reported. Canary grass, buckwheat, tares, and spring rye were grown experimentally. All results are given in tables.

Wheat sown 1 and 2 in. deep gave a much better yield than wheat sown 3 in. deep. The average results for the past 6 years were in favor of sowing 1 in. deep and at the rate of $1\frac{1}{4}$ bu. per acre. This season wheat sown with a press drill gave better results than wheat sown with a hoe drill, which accords with the average results of 6 years' tests. A larger yield of wheat was produced on fallow than on fall plowed land or spring plowed and unplowed stubble land.

In a test of mixed grain for fodder, barley and oats sown at the rate of 1 bu. each per acre produced the heaviest yield.

Flax sown May 25 at the rate of 40 lbs. per acre gave a larger yield of seed than flax sown on other dates or at different rates. The largest amount of straw per acre was obtained from a sowing made the same day at the rate of 80 lbs. of seed per acre.

An observation upon the after effect upon the growth of barley of the roots of the flat pea (*Lathyrus sylvestris*), H. J. WHEELER and J. A. TILLINGHAST (*Rhode Island Sta. Bul. 49, pp.*

51-53, *figs. 2*).—During 1898 barley was grown on 2 plats, one of which had previously been in carrots and the other in flat peas. The plat on which carrots had been grown had received 87 lbs. per acre more of nitrate of soda, 50 lbs. more of muriate of potash, and a larger amount of available phosphoric acid than the one devoted to flat peas. During 1897 the flat peas were cut twice, yielding 7,650 lbs. per acre of hay. In 1898 the two plats were prepared and fertilized in exactly the same way and seeded to barley. The growth of barley was more vigorous and the yield much greater on the plat which had previously been in flat peas than on that which had borne carrots and received more liberal fertilizing.

Experiments with crimson clover and hairy vetch, J. F. DUGGAR (*Alabama College Sta. Bul. 96, pp. 183-208, figs. 5*).—This bulletin reports the results of inoculation experiments with crimson clover and hairy vetch, and gives a general discussion on soil improving plants, the significance of root tubercles, and the inoculation of soil or seed. Brief notes regarding crimson clover and hairy vetch are given. Natural methods of inoculation and the cause for the frequent failure of Nitragin are pointed out.

Four twentieth-acre plats were used for an inoculation experiment with crimson clover. The soil was a clay loam and in a low state of fertility, and so far as known clover had never been grown on these plats nor in adjoining fields. All plats were fertilized alike, and the seed was sown on November 5 at the rate of 1 pt. per plat. No nitrogenous fertilizer was applied. Plats 1 and 3 were sown with inoculated seed, and plats 2 and 4 were sown in the usual way. The seed was inoculated by moistening it with water to which about 2 teaspoonfuls of clover Nitragin had been added. The average yield of the inoculated plats was 14,039 lbs. of green forage per acre, and of the uninoculated plats 2,293 lbs. per acre; the yield as cured hay was 4,057 lbs. and 761 lbs. per acre, respectively. Plats 2 and 4 were in part inoculated accidentally, so that the results failed to do full justice to the increase effected by inoculation.

In one experiment 2 lots of hairy vetch seed were sown, one of which was dipped into water into which had been stirred earth from a spot where vetch had grown for several years in succession. The plants from the inoculated seed made the best growth and yielded at the rate of 2,545 lbs. of cured hay per acre, while uninoculated seed yielded only 232 lbs. The inoculated plants had large clusters of tubercles on the roots, while the others had no tubercles.

In a similar experiment the seed for some plats was inoculated with vetch Nitragin. The results were similar to those obtained from seed inoculated with vetch earth. In this case the increase in yield of hay per acre as a result of inoculation was 2,706 lbs. Earth from a field of lespedeza used as inoculating material for crimson clover had no effect. It is stated that with few exceptions the inoculation of a leguminous plant can be affected only by the root-nodule bacteria from a plant

belonging to the same genus. An exception noted is the ability of the root-nodule bacteria of the garden pea to inoculate the vetch.

Rye cut when nearly mature yielded about 200 lbs. of hay per acre more than uninoculated hairy vetch grown under the same conditions.

The averages of several determinations of nitrogen in inoculated and uninoculated plants are given in the following table:

Nitrogen in inoculated and uninoculated plants.

	Nitrogen content.		Nitrogen per acre.		
	Tops.	Roots and stubble.	Tops.	Roots and stubble.	Total product.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>
Rye, nearly mature.....	0.52	0.35	16.9	9.1	26.0
Hairy vetch, uninoculated.....	1.23	1.19	2.4	4.6	7.0
Hairy vetch, inoculated.....	2.71	1.37	85.6	19.9	105.5
Crimson clover, uninoculated.....	1.62	.97	1.7	2.6	4.3
Crimson clover, inoculated.....	2.48	1.63	1.2	23.7	143.7

Fertilizer experiments with inoculated hairy vetch, using mixtures of acid phosphate and muriate of potash, as compared with no fertilizer, showed considerable increase with the potash and phosphoric acid.

“Leguminous plants . . . when amply supplied with tubercles need no nitrogenous fertilizers, but are highly responsive to acid phosphate and potash salts. These plants make heavy demands on the mineral plant food of the soil.”

Grasses and forage plants, B. C. PITTUCK (*Texas Sta. Bul. 46, pp. 1011-1030, figs. 11*).—This bulletin gives brief statements concerning the relative value of 47 species of grasses and 14 other hay and forage plants, grown in an experimental way at the station. In describing the results of the tests of sorghum and teosinte the conclusions given in a former bulletin are repeated (*E. S. R., 2, p. 742*).

Experiments on the influence of depth of plowing on the rate of seeding resulted in the best yields from broadcasting sorghum at the rate of 4 bu. per acre on land plowed 15 in. deep and broadcasting at the rate of 2 bu. per acre on land plowed 5 in. deep. Sorghum drilled in rows 3 ft. 8 in. apart at the rates of $\frac{1}{2}$ and 1 bu. per acre gave best returns on land plowed 5 in. deep, while drilling in rows 3 ft. apart at the rate of 1 bu. per acre gave best results on land plowed 15 in. deep.

Report of the State chemical-control station at Christiania, Norway, for 1897, F. H. WERENSKIOLD (*Christiania, 1898, pp. 60*).—The report gives an account of the activities of the station during the year, and contains summary statements and general discussions of the results obtained. The investigations here referred to have been continued from preceding years (*E. S. R., 9, p. 398*).

Over 300 samples of sugar beets were analyzed during the year. The samples contained from 8.47 to 14.98 per cent of sugar in the beet, the average of all analyses being 12.64 per cent. The yields obtained were small and in but few cases reached 12 tons per acre. For this reason the results of the investigation are not considered very reliable.

The results of analyses of 111 samples of root crops other than sugar beets are shown in the following table:

Composition and yield of root crops in 1897.

	Carrots (20 samples).		Kohlrabi (26 samples).		Yellow turnips (40 samples).

—F. W. WOLL.

The culture of beets on the experimental field at Grignon in 1895, 1896, and 1897, P. P. DEHÉRAIN (*Ann. Agron.*, 24 (1898), No. 2, pp. 49-83).—The work here reported consisted of variety and fertilizer tests with fodder and sugar beets. The results for each year are discussed separately and the weather conditions for each season are described. The details of the experiment and the results are given in tables. In 1895 only a few varieties of beets were tested, but drought interfered with the experiment, and but little significance is given to the results obtained.

In 1896 4 varieties of beets, including the Vilmorin sugar beet, were grown on plats which had produced wheat the preceding year. On several of these plats the effect of inoculation with nitrified soil was studied and compared with nitrate of soda. The author states that the formation of nitrates due to the action of soil ferments is insufficient in the spring for the needs of the plant, which may perhaps be due to meteorological conditions or the possible failure of the nitric ferments to become active until a month or 6 weeks after vegetation has begun to grow. A fertile soil had been taken up in the fall and kept under conditions which favored nitrification in the winter. In the spring furrows were made with a hoe between the rows of beets and the nitrified soil scattered into them at the rate of 200 kg. per hectare and covered. It is stated that the amount of nitrates thus brought to the soil is too small to have much effect, and that the

benefit resulting from such a practice must be ascribed to the activity of the micro-organisms with which the soil is inoculated. In addition to nitrified soil or nitrate of soda, both applied at the rate of 200 kg. per hectare, a general application of 20,000 kg. of barnyard manure per hectare was given. The following table shows the results obtained:

Yield of beets on plats fertilized with nitrified soil and nitrate of soda in 1896.

Variety.	Kind of fertilizer used.	Yield per hectare.	Average weight per beet.	Dry matter per hectare.	Sugar per hectare.	Nitrogenous matter per hectare.	Nitrate of potash removed in the crop per hectare.
		Kg.	Gm.	Kg.	Kg.	Kg.	Kg.
Globes jaunes.....	Nitrate of soda ...	70,000	650	8,239	5,460	581.0	51.8

In 1897 the work was continued along the same lines. Unlike the fall of 1896, the fall of 1897 was comparatively dry. The following table presents the difference in composition of the beets for the two seasons:

Comparison of the composition of beets grown in 1896 and 1897.

Variety.	Dry matter.		Sugar content.		Nitrogenous matter.		Nitrate of potash.	
	1896.	1897.	1896.	1897.	1896.	1897.	1896.	1897.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Collets roses.....	17.99	18.5	13.0	12.1	1.275	1.28	0.057	0.107
Globes jaunes	12.44	15.9	8.5	10.5	.856	1.30	.087	.237
Tankards.....	13.37	14.5	10.1	9.5	.812	.76
Vilmorin	22.50	22.3	15.5	16.6	1.666	1.31	.045	.045

The Vilmorin sugar beet varied least in composition. The Tankards were found to contain a large percentage of nitrate of potash and are considered of little value on this account. This season nitrified soil was less effective than nitrate of soda for all varieties.

A comparison of varieties of sugar beets grown this season is shown in the following table:

Density of the juice and sugar content of different varieties of sugar beets.

Variety.	Density of the juice.	Sugar in the juice.	Sugar in the beet.
		<i>Per cent.</i>	<i>Per cent.</i>
Vilmorin	70.7	17.0	16.6
Wohanka No. 1.....	70.9	18.5	17.4
Wohanka No. 2.....	70.6	19.8	18.6
Mette M. V.....	70.9	17.9	16.8
Mette M. K. V.....	70.6	17.6	16.5
Mette M. S. P.....	80.2	18.6	17.4

The average sugar content of the beets was 18.2 per cent for plats fertilized with barnyard manure, 17.8 per cent for plats fertilized with barnyard manure and nitrified soil, and 17.1 per cent for the plats fertilized with barnyard manure and nitrate of soda.

Experiments with sugar beets in Norway in 1897, B. LARSEN (*Norsk. Landmansblad*, 17 (1898), No. 7, pp. 77, 78; *Tidsskr. Norske Landbr.*, 5 (1898), No. 2, pp. 80-89).—This is a report on cooperative experiments with different kinds of sugar beets conducted under the direction of the agricultural experiment station at Aas, Norway. The experiments were made at 18 different farms. The average percentage of sugar in the beets obtained was 12.68 per cent and the average weight of beets was 358 gm. The beets grown at the Aas Experiment Station had an average sugar content of 13.19 per cent with a range from 12.7 to 13.5 per cent.—F. W. WOLL.

Experiments at the Derebchinskoe experiment field of Baron A. A. Mas, F. LYNBANSKI (*Kiev*, 1897, Vol. IX, pp. 176; *abs. in Selsk. Khoz. i Lyesov.*, 188 (1898), No. 2, pp. 471, 472).—Experiments were made to determine the influence of depth of plowing, size of seed, and the use of commercial fertilizers on the yield and quality of sugar beets. It was found that by plowing the soil at depths varying from 7 to 10½ in., the yield increased with the depth of plowing, but that the sugar content suffered a loss. Beets grown from large seed gave better yields and were richer in sugar than beets grown from small seed. A liberal use of nitrogenous fertilizers increased the yield considerably but decreased the sugar content to some extent.

A test was made of nitrate of soda as a top-dressing for oats and barley. The result showed an increase in the yield of each crop and an increase in the phosphoric acid content of the barley.—P. FIREMAN.

Experiments with sugar beets at the experiment station of Count Bobrinski at Smyela, Kiev Government, Russia, V. BOND-IRYEV (*Selsk. Khoz. i Lyesov.*, 184 (1897), pp. 165-176).—Fertilizer experiments with sugar beets were made on a Chernozem soil, rich in nitrogen and containing over 0.02 per cent available phosphoric acid but comparatively poor in potash and lime. The fertilizers, lime, potash, nitrate of soda, and superphosphate, were applied on plats of 525 sq. ft. each. The lime refuse from sugar factories was used as the lime fertilizer.

The nitrogenous fertilizer showed a tendency to deform the beets but increased the size of those parts which are rejected at the factory, while the other forms of fertilizers had the opposite effect. The sugar content and purity of the juice was decreased by the use of the nitrogenous fertilizer and lime, but the yield of beets was increased to some extent. The potash and superphosphate improved the quality and increased the quantity of the crop. The greatest increase in sugar was due to the potash fertilizer.

The results of other experiments conducted show that plowing 14 in. deep for sugar beets was better than plowing 10½ in. deep.—P. FIREMAN.

Experiments on sugar beets in the Royal School of Agriculture at Portici (*Bol. Not. Agr., 19 (1897), I, No. 28*).—Experiments with sugar beets are described and the results tabulated and discussed. The use of commercial fertilizers increased the sugar content but not to a great extent, and this result is attributed to unfavorable weather conditions and to the fact that the fertilizers were not applied long enough before planting. The Vilmorin Improved sugar beet gave the best results among 4 varieties tested. The latter part of August was found to be the best time for harvesting beets.

Tobacco, J. CRAIG (*Canada Expt. Farms Rpt. 1897, pp. 131-133*).—The work consisted of culture and fertilizer tests, and experiments on the time of topping and the number of leaves to allow each plant. Tobacco plants transplanted into hot beds and cold frames before setting them out in the field gave yields so nearly alike that no conclusions are drawn. Among the different fertilizer experiments the largest yield of green leaf was obtained from an application of superphosphate, wood ashes, and nitrate of soda mixed in the proportion of 15, 15, and 5 lbs. respectively, and applied at the rate of 10 lbs. to 24 plants.

Plants were cut back to 9 and 11 leaves on July 20 and 26 and August 2. The larger yields were obtained from the later topping and the greater number of leaves.

Experiments with wheat, J. S. NEWMAN and C. M. CONNER (*South Carolina Sta. Bul. 37, pp. 1*).—Experiments with wheat, comprising variety tests and a comparison of broadcasting and drilling seed were conducted for 2 years. The wheat was sown in the fall. The results are given in tables and the 7 varieties tested are described. Red Winter gave the best yield in all tests—21 bu. per acre in the variety test and 30.2 and 25.2 bu. for the broadcasted and drilled plats respectively. Lancaster and Red May stood first among the varieties tested for 2 years, yielding on an average 15.1 and 12.3 bu. per acre respectively. On the drilled plats the grain came up more evenly than on the broadcasted plats.

Wheat (*Kentucky Sta. Bul. 77, pp. 109-120*).—The experiments reported consisted of variety and fertilizer tests of wheat. The meteorological conditions of the season and the results of the experiments are given in tables (*E. S. R., 9, p. 639*). Notes on all varieties and detailed descriptions of the varieties not described in former bulletins are given.

Twenty varieties were grown on twentieth-acre plats in drills 7 in. apart. The seed was sown at the rate of 1½ bu. per acre October 25. Jones Winter Fife, Early White Leader, American Bronze, and Bearded Winter Fife were the most productive, yielding 22.3, 19, 18.5, and 18.2 bu. per acre respectively. The weight per bushel for these varieties ranged from 60.2 to 64 lbs., Bearded Winter Fife being the heaviest.

Jersey Fultz and Extra Early Oakley, yielding 17.8 and 15.2 bu. per acre and weighing 64.7 and 64.2 lbs. per bu. respectively, were rated as first grade milling varieties.

Fertilizers had no appreciable effect on the yield of grain or straw at the station. A fertilizer experiment made in the western coal measures of the State indicated the need of phosphoric acid; potash had little if any effect.

Field experiments with wheat, W. C. LATTA and W. B. ANDERSON (*Indiana Sta. Bul. 72, pp. 67-76, dgm. 1*).—This bulletin gives the results of variety tests of wheat in 1897-98, and a résumé of field experiments with fertilizers on wheat. In the aggregate 27 varieties of wheat were tested in the 2 seasons. New Columbia, Early Ripe Hybrid, Prolific, and Harvest King produced straw of good strength, and Velvet Chaff, Michigan Amber, Early Ripe Hybrid, Prolific, and Harvest King were practically free from scab which was very prevalent in the locality of the station. Velvet Chaff and Michigan Amber have been grown for 15 years in succession, yielding on an average 29.08 and 28.94 bu. per acre, respectively. So far these 2 varieties have shown no signs of deterioration.

Applications of mixed fertilizer and horse manure were made on 5 series of plats. The series contained 7 plats each and were under different systems of cropping. The mixed fertilizer furnished approximately 2 parts of phosphoric acid, 4.5 of nitrogen, and 3 of potash. In each series 2 plats were fertilized with the mixed fertilizer, 2 with horse manure, and 3 received no fertilizer. The effect of the systems of cropping and the methods of fertilizing are shown in the following table:

Average yield of wheat on fertilized and unfertilized plats.

System of cropping.	Average yield per acre of unfertilized plats.	Average yield per acre of fertilized plats.	Increase over unfertilized plats.
	<i>Bushels.</i>	<i>Bushels.</i>	<i>Bushels.</i>
Corn and wheat in alternate years	15.68	28.95	13.86
Three course: Corn, oats, wheat.....	23.44	30.28	7.87
Wheat grown continuously.....	16.45	21.00	4.72
Four course: Corn, oats, wheat, clover.....	20.41	26.37	6.23
Corn, beets, oats, wheat, grass	24.20	28.32	4.72

A comparison was made of the light and heavy applications of fertilizers and horse manure, and of the cost per bushel of increase in yield with the same. This showed the horse manure to be the more economical.

Sowing field crops at different rates in Russia (*Rpt. Min. Agr. and Govt. Estates, Division of Rural Economy and Agricultural Statistics, St. Petersburg, 1897, pp. X+50+213, abs. in Selsk. Khoz. i Lyesov., 190 (1898), pp. 717, 718*).—This article treats of sowing grains at different rates, and gives the opinion of practical men in this connection.

It is stated that in hot dry seasons thinly sown crops are more successful than thickly sown crops, and that in southern and southeastern Russia, where the climate is rather dry, crops are usually thinly sown. When the soil is adequately moist and the grain is sown early, thin sowing may be practiced. In general favorable soil conditions and rational methods of sowing tend to decrease the amount of seed necessary to sow a given area.—P. FIREMAN.

The chemistry of the corn kernel, C. G. HOPKINS (*Illinois Sta. Bul. 53, pp. 129-180, fig. 1*).—*The proximate composition of corn* (pp. 130-157).—Following a résumé of the work of various investigators, beginning with that of Gorham in 1821, the author gives the results of his studies on the proximate composition of the corn kernel, describing incidentally the methods of analysis employed, some work on the determination of water and of nitrogen (see p. 819), sampling, and a condenser for use in fat determination (see p. 820).

Ten analyses of pint samples of corn of a single variety grown under uniform conditions "showed a marked degree of uniformity;" but analyses of 50 separate ears of Burr White corn from a uniform field varied widely and "seem to bring out and clearly to establish the fact that there are extreme variations in the chemical composition of corn grown from the purest seed of a single variety and under markedly uniform field conditions." The variations in these samples are shown below:

Variations in the proximate composition of 50 different ears of Burr White corn grown under uniform conditions.

	Ash.	Protein.	Fat.	Carbohydrates.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Maximum	1.74	13.88	6.02	85.79
Minimum	1.09	8.35	3.95	78.92
Difference.....	.65	5.53	2.07	6.87

"With every constituent the variation is greater than Flechig found with 13 different varieties, and it is nearly as great as found by the Connecticut Experiment Station with about 75 different varieties of corn grown under 90 presumably different conditions."

Thirty duplicate analyses were made of kernels from different parts of ears, dividing the ears lengthwise and into tip, middle, and butt; and in addition the ash and protein were determined in single kernels from different parts of the ear, ears being selected which were relatively high and low in these constituents.

"The concordant evidence of 30 duplicate analyses of parts of ears, of 50 ash determinations, and of 50 protein determinations in single kernels would seem to warrant the conclusion and to establish the fact that the composition of the ear is approximately uniform throughout."

The complete composition of corn (pp. 157-180).—This part consists of

a compilation of studies on the ash constituents, proteids, and carbohydrates of the corn kernel, together with an account of the author's investigations on the oil of corn (see p. 817).

Clovers as green manures, F. T. SHUTT (*Canada Expt. Farms Rpt.*, 1897, pp. 138-146, pl. 1).—Experiments were made in green manuring and in soil inoculation. A number of plats were sown to barley and clover and the total clover residue, comprising the dead stems and leaves and the roots to a depth of 9 in., and the amounts of fertilizing constituents contained in this residue the following spring were determined for each plat. Mammoth red clover was sown on 6 plats at different rates, but the plat sown at the rate of 10 lbs. per acre, although not giving the largest amount of total residue, furnished the largest amounts of fertilizing constituents. In the following table the data for the other plats sown with this variety are omitted. The clover residue was collected May 1.

Fertilizer constituent per acre in the residue of different varieties of clover sown with barley.

Variety.	Seed per acre.	Composition.				Residue per acre.	Fertilizing constituents per acre.		
		Water.		Organic matter.			Organic matter.	Ash.	Nitrogen.
		<i>Lbs.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>				
Mammoth red	10	59.43	33.19	7.38	1.417	5,955	1,978	439	81
Common red	10	72.50	23.61	3.89	1.016	6,125	1,446	238	62
Alsike	6	71.58	22.63	5.79	1.020	3,233	732	187	33
Crimson	24	62.82	33.01	4.17	.827	1,322	478	60	12
Alfalfa	14	61.54	34.79	3.67	1.075	2,212	772	79	26

Inoculation experiments were made with Nitragin on horse beans and mammoth red clover grown in pots. In each case plants were grown on inoculated and uninoculated soil and from inoculated seed. The results in each case were in favor of inoculation. Soil inoculation produced the largest yields in the test with horse beans and seed inoculation in the trial with clover.

Experiments in fertilizing meadows (*Selsk. Khoz. i Lyesov.*, 184 (1897), No. 2, pp. 457-160).—Fertilizer experiments with nitrate of soda, superphosphate, kainit, Thomas slag, compost, and barnyard manure were made on a meadow which was divided into 26 plats of three-tenths acre each. The soil was sandy, but contained a good proportion of humus. From the results obtained for 2 years, it is concluded that the use of nitrate of soda alone increases the yield of hay but slightly, while with kainit or with superphosphate and Thomas slag its action becomes more marked. The use of 640 lbs. of superphosphate gave an increase of 2,816 lbs. of hay per dessiatine (2.7 acres). Superphosphate was most effective when applied in conjunction with kainit and with kainit and nitrate of soda. An application of 1,720 lbs. of Thomas slag per dessiatine resulted in an average increase of 2,800 lbs. of hay, while an application of 960 lbs. increased the yield 2,460 lbs. Kainit alone scarcely increased the yield, but 1,600 lbs. of kainit per dessiatine

applied with phosphatic fertilizers produced an increase of 2,000 lbs. in the yield of hay. Compost and barnyard manure exerted a good influence only in the second year.—P. FIREMAN.

Fertilizer experiments with lime, F. H. WERENSKIOLD (*Norsk. Landmansblad*, 17 (1898), No. 13, pp. 135-138).—Cooperative fertilizer experiments were conducted on sandy clay and marshy soils. The plats were 0.247 acre in size and one-half of each plat received a dressing of 300 kg. of lime. The plats on clay soil received in addition to the lime an application of 75 kg. of Thomas slag and 25 kg. of nitrate of soda, while those on marshy soil received Thomas slag and kainit. Düppauer oats were grown on all plats. The chemical composition of the different crops showed marked variations which could not be accounted for by the difference in fertilization.—P. W. WOLL.

Farm crops at the experimental farm for the maritime provinces, G. W. FOREST (*Canada Expt. Farms Rpt. 1897*, pp. 273-286).—The work here described is similar to that previously reported (E. S. R., 9, p. 832). The results of variety tests of spring wheat, barley, oats, peas, mangel-wurzels, carrots, sugar beets, potatoes, corn, and millet, and the results of early, medium, and late sowings of wheat, barley, and oats are tabulated. General statements of the weather conditions and the culture, growth, and yield of the different crops are made.

Farm crops at the experimental farm at Agassiz, British Columbia, T. A. SHARPE (*Canada Expt. Farms Rpt. 1897*, pp. 405-420).—The work here reported in tabular form consists of variety tests and tests of early, medium, and late sowings of spring wheat, oats, barley, and peas, and variety tests of corn, turnips, mangel-wurzels, carrots, sugar beets, potatoes, and fodder crops. Similar work has been previously reported (E. S. R., 9, p. 833).

Report on crops, live stock, etc., in Manitoba (*Dept. Agr. and Immig. [Manitoba] Bul. 57*, pp. 28).—A brief report on the yield of the various kinds of grain and the meteorological conditions for 1898.

The cotton crop of 1897 and 1898 (*U. S. Dept. Agr., Division of Statistics Circ. 9*, pp. 16).—This circular is a report on the cotton crop of the United States in 1897 and 1898. The movement of the cotton crop by rail, water, and wagon is shown for each State, and other statistical data comprising comparative acreage and production in 1896 and 1897, the consumption of American cotton by foreign countries, the yields, cotton consumption, and the number of spindles in operation in 1898 in different countries are given. The crop for this season amounted to 10,821,578 bales of upland cotton and 76,279 bales of sea island or a total crop of 10,897,857 bales produced on 24,319,584 acres.

Cotton, corn, wheat, and forage crops, H. BENTON (*Alabama Canebrake Sta. Bul. 18*, pp. 3-12).—The results of miscellaneous experiments with various crops in 1894 are briefly stated.

Review of literature on plant culture, L. OCHAPOVSKI (*Selsk. Khoz. i Lysov., 188* (1898), No. 3, pp. 203, 204).

Jerusalem artichokes grown in the same field for twelve successive years, M. G. LECHARTIER (*Ann. Sci. Agron., 1898*, 1, No. 1, pp. 121-154).—The results for each year are given separately. The composition of the different parts of the plant in the fresh and dry state is given and the effect of fertilizer applications on the crop is discussed. It is concluded that Jerusalem artichokes can be successfully grown on the same field without interruption for a series of years with the aid of commercial fertilizers. Applications of commercial fertilizers gave better returns than barnyard manure or mixtures of commercial fertilizers and barnyard manure.

Awnless brome grass (Bromus inermis), J. FLETCHER (*Canada Expt. Farms Rpt. 1897*, pp. 229, 230).—A popular description of the species and of its importance in connection with the forage problem in the western prairie region. "Under irri-

gation . . . brome grass has given on 200 acres of land the enormous yield of 4½ tons of grass per acre."

Review of literature on the culture of beets, L. OCHAPOVSKI (*Selsk. Khoz. i Lysov.*, 189 (1898), No. 1, pp. 171-202).

Clover and grass mixtures for meadows and pastures, WERNER (*Mitt. Deut. Landw. Gesell.*, 14 (1899), No. 2, pp. 11-15).—This article describes a number of clovers and grasses and points out their adaptability to certain soils and uses. A number of clover and grass mixtures for meadows and pastures on different soils are suggested.

Cowpea ensilage, T. C. CRENSHAW, jr. (*Country Gent.*, 64 (1899), No. 2403, pp. 121, 125).—The method of ensiling cowpeas is discussed and the value of cowpea silage pointed out.

Kafir corn, C. K. McQUARRIE (*Florida Agr.*, 26 (1899), No. 10, pp. 146, 147).—A popular article on growing Kafir corn in Florida.

Review of literature on the culture of potatoes, L. OCHAPOVSKI (*Selsk. Khoz. i Lysov.*, 188 (1898), No. 3, pp. 641-672).

Variety tests of potatoes in 1898, W. BLUMICH (*Sächs. Landw. Ztschr.*, n. ser., 21 (1899), No. 6, pp. 62, 63).—A report on the results.

Observations on the yield and starch content of several varieties of potatoes, A. GIRARD (*Ann. Sci. Agron.*, 1898, I, No. 1, pp. 46-83).—A number of varieties of potatoes were grown for 10 successive years and the yields and starch content of each variety for each year are reported. It was found that a dry season decreased the yield but increased the starch content, while a wet season had the opposite effect. The varieties recommended, given in their order, are Richter Imperator, Red Skinned, Idaho, and Géante sans Pareille.

Importance of good seed in sugar-beet cultivation, H. W. DIEDERICH (*U. S. Consular Rpts.* 1898, No. 218, pp. 451-454).—This article discusses sugar-beet-seed production in Germany with reference to the needs of the American sugar-beet grower, and advises planting seed of high grade and pure pedigree.

Distance experiments with sugar beets, F. DESPREZ (*Jour. Agr. Prat.*, 1899, II, No. 4, pp. 125-127).—It is concluded that the distance between plants is a direct factor in the cost of producing sugar, but that no fixed rule can be laid down, as different distances are required under different conditions.

A new method of growing sugar beets for seed, H. BRIEM (*Bt. Zuckerrübenbau*, 6 (1899), No. 1, pp. 1-4).—A general review of the different methods of growing seed beets, with an outline of a new method.

Cultivation of sugar cane in the Bombay Presidency, J. W. MOLLISON and J. W. LEATHER (*Agr. Ledger (Agr. ser.)*, No. 25, 1898, No. 8, pp. 69).—Notes on the cultivation of sugar cane, with descriptions of varieties.

The classification of wheat, A. SEMPOLŌWSKI (*Deut. Landw. Presse*, 26 (1899), No. 12, p. 103).—A discussion of the classification of wheat and an outline of Eriksson's system of the classification of varieties.

Investigations on the injurious effects of hail on wheat and barley, C. KRAUS (*Deut. Landw. Presse*, 26 (1899), No. 14, pp. 137, 138; 15, pp. 149, 150, figs. 4).

Plowing and harrowing, G. HEUZÉ (*Jour. Agr. Prat.*, 1899, I, No. 7, p. 240).—A note on the importance of plowing and harrowing in connection with various crops and rotations.

The use of the land roller in plant culture, E. WOLLNY (*Fühling's Landw. Ztg.*, 48 (1899), No. 2, pp. 47-50; 3, pp. 85-91).—The results of experiments show that rolling cereal crops after certain stages of development materially decreases their productive capacity, while the effect during the earlier stages of growth was less marked and in 1 instance slightly increased the yield. Rolling the potato crop during the early stages of growth had a beneficial effect, but when the growth of the plants was advanced the results of rolling did not prove conclusive. The effects of rolling the potato crop varied with different seasons. In general, rolling decreased the number of diseased tubers.

The chemistry of the corn kernel, C. G. HOPKINS (*Illinois Sta. Bul. 53—Abstract, pp. 4, fig. 1*).—An abstract of Bulletin 53 of the station (see p. 844).

Report on experimental manuring, J. A. MURRAY (*Aberystwyth: University College of Wales, 1897, pp. 28*).—Results of cooperative fertilizer experiments on grass, mangel-wurzels, Swedish turnips, and turnips are reported.

Fertilizer experiments with kainit, B. SCHULZE (*Jahrb. Agr. Chem. Vers. Stat. Breslau, 1896; abs. in Centbl. Agr. Chem., 28 (1899), No. 2, pp. 90-92*).—The results of numerous cooperative experiments on potatoes in different parts of Germany in 1896 are reported. The yield was not increased to an important degree by kainit applied to the previous crop. The starch was invariably decreased with the large applications of kainit (1,781.4 lbs. per acre) and usually with the smaller applications (890.7 lbs. per acre).

Fertilizer experiments with potash salts, H. WEHNERT and A. EMMERLING (*Jahrb. Landwirtschaftskammer, Schleswig-Holstein, 1897; abs. in Centbl. Agr. Chem., 28 (1899), No. 2, pp. 92-95*).—Experiments of the same character as those of Schulze, noted above, led to the conclusion that applications of 890.7 lbs. of kainit per acre do not injuriously affect the starch content of potatoes, although the use of double this amount reduced the amount of starch. The economy of using larger amounts is considered doubtful.

The latest information regarding the use of commercial fertilizers in beet culture, J. STRITESKY (*Neue Ztschr. Rübenz. Ind., 42 (1899), No. 3, pp. 21-24*).—A general discussion of the subject.

Top-dressings of sulphate of ammonia and nitrate of soda, KLOEFFER (*Fühling's Landw. Ztg., 48 (1899), No. 3, pp. 114-116; 4, pp. 138-142*).—Sulphate of ammonia and nitrate of soda were applied as a top-dressing to winter wheat in the spring, the sulphate of ammonia being applied about the middle of March, while the nitrate of soda was applied about 1 month later. The records of 5 tests show that the use of sulphate of ammonia was more effective than the use of nitrate of soda.

HORTICULTURE.

Report of the horticulturist, J. CRAIG (*Canada Expt. Farms Rpt. 1897, pp. 90-103, 121-130, figs. 7*).—Descriptions are given of 7 seedling black currants: Beauty, Standard, Success, Monarch, Climax, Star, and Winona, which after 7 years' trial are believed to be superior to any commercial varieties of the same season. These have been selected from about 150 seedlings produced by W. Saunders in 1884.

Ten American and 107 English gooseberries and a few hybrids have been tested since 1893. Few of the English varieties have succeeded. A table gives notes as to the hardiness and health of plants and the color of fruit for 65 varieties of gooseberries. The following varieties are recommended: Red Jacket, King of Trumps, London, Speedwell, and Riccardo.

A test of thinning peaches and plums, made by M. Burrell at St. Catharines, Ontario, is reported. Three six-year-old Hyne Surprise peach trees were chosen; one was thinned June 22, one 10 days later, and the third left unthinned. On the thinned trees the fruit was left about 2 in. apart. At the time of thinning, the fruit on the tree first thinned was $\frac{1}{2}$ to $\frac{2}{3}$ in. long and on the tree thinned later, 1 to $1\frac{1}{4}$ in. long. Thinning was found to increase the total yield and the size of fruits and to decrease the amount of rot. Three trees of Moore Arctic plum were treated similarly to the peach trees. The results

gave the same indications as the peaches though not so marked. The author says: "In both cases it will be observed that the early thinning bore the most profitable results, and it will manifestly pay to commence work of this kind immediately after the fruit sets." A test of thinning apples and plums at the Central Experimental Farm emphasized the results obtained by Mr. Burrell.

A series of trials of methods of storing apples was conducted during the season of 1896-97, beginning in the fall and continuing until the last of July. The tests included 24 varieties of apples and were planned to test the following points: Wrapped *vs.* unwrapped fruit, cellar *vs.* ground floor storage, and close *vs.* ventilated packages. "Specimens wrapped in paper kept best, there were fewer rotten apples, and they lost least by evaporation. The ground floor storeroom did not preserve them as well as the cellar. . . . The tight package preserved the fruit best in storeroom but not in cellar; *per contra* the ventilated did better in cellar than in storeroom." Twenty-six varieties of apples are classified according to their keeping qualities.

Notes are given on some cover crops for orchards. Mammoth red and common red clover completely winterkilled in January, 1896. Alfalfa fared somewhat better. It was noted that where mammoth red clover and alfalfa plats overlapped, both crops came through the winter better than where growing separately. The next fall plats were sown with clover and alfalfa mixed in equal parts. Of the mixture the author says, "The one formed an appropriate complement to the other, the spreading stools of the mammoth red covering the ground with a thick mat beneath the more slender and taller growing alfalfa."

Tests of 48 varieties of bush beans, 19 of pole beans, 11 of Lima beans, 25 of celery, 5 of celeriac, 23 of cucumbers, and 23 of onions are reported in tables, accompanied by brief notes. Cultural experiments were also made with a number of vegetables. Seed of peas and beans was soaked 1 hour in solutions of nitrate of soda of different strengths, 1, 2, and 3 oz. of the salt to 1 gal. of water, to ascertain the effect on germination and yield. With peas the percentage of germination was not affected by the treatment, but with the exception of one variety there was a regular increase in yield with the increased strength of solution used. The results with beans were too variable to justify conclusions.

A test of growing a number of varieties of celery in spent hotbed *vs.* cold frames is reported. The average weight per stalk of the hotbed-grown plants was 11 oz. while that of the cold frame plants was over 1 lb. There was little difference as regards quality.

Sowing onion seed at various dates in the hotbed and transplanting the plants into the field was compared with sowing the seed directly in the field at various dates. Transplanting increased the total yield and decreased the quantity of unmerchantable onions.

Trial shipments of fruit (*Rpt. Comr. Agr. and Dairying, Canada, 1897, pt. 7, pp. 20, figs. 2*).—The results of trial shipments of various fruits from Canada to Great Britain are reported. The article gives

quantities of fruit shipped, names of shippers, varieties of fruit, freight charges, prices from some sales, extracts from letters reporting on pears, peaches, tomatoes, grapes, and apples, with a report on shipments of apples, the average prices received, etc. Some of the conclusions are as follows:

"The value of tender fruits in Great Britain depends chiefly upon their condition. To insure the preservation of their condition at its best, it is necessary that a suitable package should be used. It should be (1) strong enough to provide for safe carriage, (2) so constructed as to provide for thorough ventilation, (3) cheap, and (4) of a size convenient for handling. No one package is suitable for all kinds of fruit; but the package for the carriage of every sort of fruit should meet these requirements. . . . Care should be taken in the handling of all tender fruits to prevent bruising. The sorting and wrapping should be done in such a way as to involve the least possible handling of the fruit. If the fruit can be cooled before it is sorted and wrapped so much the less will be the risk of injury. The packing of the fruit should be done in such a way as to keep it firm in the package. An excess of packing, in so far as that prevents circulation of air, is objectionable. Some kinds of packing are liable to become moldy from the dampness caused by evaporation from the fruit. Paper and excelsior packing are of that sort. . . . All tender or soft varieties of fruit should be cooled as quickly after it is picked as is practicable. For long keeping they should be cooled to a temperature between 36 and 40° F., as warm fruit generates heat by the changes which proceed in it. . . . Packages containing warm fruit should never be loaded close in a railway car in warm weather. If a refrigerator car be used, well iced, the generation of heat in cases of warm fruit will more than counterbalance the cooling power of the ice. The fruit will continue to ripen and decay will begin. . . .

"Early ripening and soft varieties of apples should be packed in ventilated barrels or boxes and sent in cold storage. Otherwise a large proportion of them are likely to arrive in a slack and wet condition and to be sold for a price which can entail only loss. . . . The later and firmer varieties of apples can be shipped safely if cooled below 50° F., packed in ventilated barrels, and carried in the holds of steamships provided with air ducts for causing thorough ventilation. . . . Less attention is paid in Great Britain to the variety of pears than to the soundness and nice appearance of the fruit. Pears of a typical and regular shape are wanted and from a medium to a large size. From the trial shipments it appears that a large trade can be created at prices which will be remunerative to the growers here. . . . Tender varieties of peaches, such as Crawfords, can be shipped with safety only when the fruit is picked in a firm condition and cooled to a temperature of under 40° soon thereafter. . . . Tomatoes can be shipped safely. The price that may be obtained regularly will depend so much on the supplies available from other countries that no safe estimate can be made. Those varieties which are of medium size, smooth and regular in shape, solid, with small seed cavities, sell for the highest prices. In the trial shipments last year tomatoes of small size were sold at 9s. 4d. per case, when tomatoes of large size at the same time sold for only 6s. 8d. per case. . . . Fruit intended for Great Britain should be picked when fully grown and when beginning to change color. If provision has not been made for the carriage of it in cold storage, the fruit should be picked and packed when of full size, but while still a green color and well glazed. . . . Each tomato should be wrapped in tissue paper or in a light, cheap grade of printer's paper. They should be carefully packed stem end down, so that each one will be held firmly in place when the case is closed. It is doubtful whether a profitable trade can be developed in the shipment of plums from Canada. . . . From the quotations from letters of those to whom Canadian grapes were shipped last season it is evident that there is not yet a demand for them in Great Britain."

The date palm, J. W. TOUMÉY (*Arizona Sta. Bul.* 29, pp. 102-150, figs. 13).—Notes are given on the early history of the date palm, the history of the date palm and some of its seedlings in Arizona, the distribution and present condition of the date palm suckers imported by the Department of Agriculture in 1890, of which 39 are now living, methods of propagation and growth, distinction of the sexes, the fruit of the date palm, which varies greatly in many respects, imports of dates since 1860, and insects and other enemies of the date, making especial mention of a scale insect (*Parlatoria victrix*) introduced on imported palms and considered the most serious enemy of the date palm in this country. An especial study is made of the climate to which the date palm is adapted. The climatic conditions in countries where the date palm is native are stated and the conditions in southern Arizona studied comparatively. Tables are given showing the average annual precipitation and mean monthly maximum and minimum temperature at 3 stations in southern Arizona and 6 stations in northern Africa for a period of years. These show a great similarity between the climatic conditions of southern Arizona and the regions adjacent to the Sahara Desert. Not merely these theoretical considerations, but the experimental fact that date palms from both seedlings and imported suckers are now growing and fruiting satisfactorily in various localities, make it probable that date culture will, in time, become an important industry over considerable areas of the interior arid region of the Southwest, of which southern Arizona may be considered the center. As an ornamental tree the date palm flourishes as far north as San Francisco and southern Colorado, but produces fruit of value only in arid regions where the air is dry and summer heat intense. Abundance of water within reach of the roots is necessary to the fruit's perfection. In a comparative study of the soils of the date regions of northern Africa and southern Arizona, it is found that both possess 2 essential features for date culture, namely, paucity of humus and abundance of alkali.

Results of experiments in the cross fertilizing of plants, shrubs, and trees, W. SAUNDERS (*Canada Expt. Farms Rpt.* 1897, pp. 60-67, 69, 70, figs. 16).—This article was read before the British Association for the Advancement of Science, August, 1897. The writer reports work which was begun in 1868 and has been continued at intervals since then.

American varieties of gooseberries were crossed with European varieties with the object of improving the size and quality of the fruit, and obtaining varieties unaffected by mildew, which damages the European sorts so severely. Of several hundred seedlings, Pearl and Red Jacket have become popular sorts both in Canada and the United States. Attempts to cross the European gooseberries with the wild smooth gooseberries (*Ribes oxycanthoides*) were unsuccessful. With the wild prickly gooseberry (*R. cynosbati*), a number of interesting hybrids were

obtained having the habit of growth of the wild sort but with fruit improved in size and quality.

Hybrids between the white currant (*R. rubrum*) and the black currant (*R. nigrum*), and between the latter and the cultivated gooseberry (*R. grossularia*), were obtained. Of the latter, 28 are still under trial. In all these hybrids the black currant was used as the pistillate parent. The hybrids have the thornless branches of the black currant, but as regards the leaves, flower clusters, and pistils are intermediate between the 2 parent forms. Hybrids of the cultivated black currant and the western wild black currant (*R. floridum*) have characters more or less intermediate between the 2 parents, and some of them appear worthy of cultivation for their fruit.

About 400 hybrids of native and improved American grapes from pollen of European grapes were secured. Many of them were not hardy; some lacked in vigor, some in quality of fruit, and many others bore only staminate flowers. Only a few of these are worthy of cultivation. One of them, the Kensington, is especially productive, has the vigor of growth, character of foliage, and hardness of the American grape Clinton, and its fruit is intermediate between the Clinton and the European Buckland Sweetwater. Hybrids of the American grape Concord from pollen of European sorts have the long, leathery, downy leaves of the former, with fruit very variable in appearance and quality.

Crosses of red raspberries were all tender and unhealthy. Twenty-four hybrids of the black raspberries (*Rubus occidentalis*) with pollen of the red raspberry (*R. strigosus*) were obtained. All the seedlings rooted from the tips, though less freely than the black raspberries, and a few produced an occasional sucker similar to the red raspberry. The fruit was larger than either parent, of a dark purple color, and combined the flavor of the 2 parents. Most of the efforts to cross the red raspberry with the blackberry (*R. villosus*) were unsuccessful. In several cases seeds were produced, but only part of them germinated and the seedlings were very weak.

Attempts to hybridize apples and pears were unsuccessful. The same was true of attempts to cross the plum with the peach and the plum with the cherry. Crosses of different classes of cherries were only partially successful. Attempts to cross the sand cherry (*Prunus pumila*) with various varieties of the cultivated cherries failed, but a single cross of the sand cherry and the wild plum (*Prunus americana*) was successful. In foliage the hybrid is intermediate, resembling most the plum. A number of crosses have been secured between the more hardy cultivated apples and crab apples and the small Siberian crabs (*Pyrus baccata* and *P. baccata prunifolia*). The hybrids vary considerably, some resembling one parent and some another. None have yet fruited.

Hybrids of the Japanese barberry (*Berberis thunbergii*) and the purple barberry (*B. vulgaris purpurea*) were intermediate between the parents in character of thorns, leaves, flowers, and time of blossoming.

Attempts to hybridize wild and cultivated species of verbena and aquilegia were successful. With the latter many distinct intermediate forms were obtained. Similar attempts with wild and cultivated geraniums were unsuccessful.

The author also reports results of work with various cereals and peas (E. S. R., 10, p. 835).

Horticultural conditions in Europe, L. H. BAILEY (*Rural New Yorker*, 58 (1899), No. 2559, pp. 93-95).

Practical arboriculture, TRONCET and DELÈGE (*Arboriculture pratique*. Paris: Librairie Larousse, 1898, pp. 163, figs. 190).—A popular work.

Report of the horticulturist of the experimental farm for the maritime provinces, W. S. BLAIR (*Canada Expt. Farms Rpt.* 1897, pp. 288-306).—Lists of varieties of various fruits and ornamental plants planted at the farm are given, together with a brief note on the present condition of each. Notes are given on the best varieties of a number of garden vegetables tested at the farm.

Vegetables, flowers, fruits, shrubs, and trees at the experimental farm for the Northwest Territories, A. MACKAY (*Canada Expt. Farms Rpt.* 1897, pp. 380-398, pl. 1).—Notes and tabular statements regarding varieties of the plants named above are given.

Fruits, flowers, vegetables, shrubs, and trees at the experimental farm for Manitoba, S. A. BEDFORD (*Canada Expt. Farms Rpt.* 1897, pp. 336-353, pl. 1).—Brief notes and tabular statements in regard to varieties of the above plants are given.

Truck farming, R. H. PRICE (*Florida Farmer and Fruit Grower*, n. ser., 11 (1899), No. 6, pp. 84, 85).—Cultural notes on the cantaloupe, tomato, Irish potato, cabbage, snap bean, and sweet potato, which are stated to be among the vegetables that can be grown with profit in the coast regions of Texas and bear shipping a long way.

The vegetable garden, L. J. TRONCET (*Le jardin potager*. Paris: Librairie Larousse, 1898, pp. 181, figs. 190).—A popular work. A number of the illustrations are lithographed in colors.

The forcing of vegetables, N. BUTTERBACH (*Amer. Gard.*, 20 (1899), No. 217, pp. 121, 122).—A continued article giving practical directions for the forcing of vegetables, together with lists of varieties adapted to this purpose.

The eggplant (*Solanum melongena*), A. ZEGA (*Chem. Ztg.*, 22 (1898), No. 92, p. 975, figs. 2).—Notes on the size, morphology, and culinary preparation of the fruit of the eggplant. The chemical analyses of 6 samples are tabulated and these are compared with analyses of fruit grown from Japanese seed, which latter contained more water. Notes are also given on the extraction of the coloring matter from the outer layer of the fruit.

The evolution of our native fruits, L. H. BAILEY (*New York: The Macmillan Co.*, 1898, pp. 472, figs. 125).—This is a companion volume to the author's *Survival of the Unlike*, and endeavors to show how leading types have come to be. The subjects treated are: The rise of the American grape, the strange history of the mulberries, the evolution of American plums and cherries, the native apples, the origin of American raspberry growing, and the evolution of blackberry and dewberry culture. Various types of berry-like and tree-like fruits more lightly touched upon are the gooseberry, native currants, juneberry, buffalo berry, elderberry, high-bush cranberry, cranberry, strawberry, persimmon, custard apple, thorn apple, and nut fruits. In each case the native species, their distribution and feral variations are discussed. These considerations furnish a key to the origin of many of the cultivated races. Other races are traced back to their origin as a stray seedling, or a hybrid, feral or otherwise. Much prominence is given to the work of those pioneer experimenters who have been most instrumental in the amelioration of native fruits. The work thus

partakes not a little of the nature of historical narrative, and interest in this narrative is much enhanced by the author's lucid and entertaining style. Appended to the description of the American grape are a synopsis of the American species of grapes and a bibliography of American grape literature. Much attention is given to the analysis of the complex relationships existing within the genus *Prunus*. The author's study of the American Rubi has brought to light a surprising confusion in the nomenclature of the blackberry and dewberry group. He has personally identified the type specimens of this group in European herbaria, and has thoroughly revised the nomenclature to agree with them. The concluding chapter of the book, general remarks on the improvement of our native fruits, is a reprint with minor modifications of a paper originally contributed to the 1896 Yearbook of this Department, pp. 297-301 (*E. S. R.*, 9, p. 558). In tracing the evolution of the native American fruits the author has brought to light many facts of great historical interest and has called attention to the opportunities that await the explorer in the field of history of agriculture.

A new fruit (*Salpichroa rhomboidea*), F. W. BURBRIDGE (*Sci. Amer. Sup.*, 47 (1899), No. 1201, p. 19-27).—This fruit, which is also known as *Withania* and belongs to the Solanaceae, is said to be ovoid, "about the size of a small olive, the skin being, when ripe, pale yellow, and filled with soft pulp and seeds." It is said to taste "like a combination of nectarine and pineapple, with a dash of melon thrown in." It is believed that the fruit will never become of much economic value.

Fruits at the experimental farm for British Columbia, T. A. SHARPE (*Canada Expt. Farms Rpt. 1897*, pp. 420-433).—Data in regard to varieties of various fruits are given in notes and tables.

Fruits, H. BENTON (*Alabama Canebrake Sta. Bul. 18*, pp. 12-15).—A list of fruit trees planted on the station grounds. Certain varieties of apples, pears, and grapes are recommended as especially adapted to the soil and climate.

History of the Yellow Newton apple (*Montana Fruit Grower*, 8 (1899), No. 37, p. 1).—Historical and descriptive notes.

Report on plums, G. VESTAL and F. GARCIA (*New Mexico Sta. Bul. 27*, pp. 117-132).—This bulletin gives directions for plum culture. The subjects discussed are soil for plums, the best stocks for plums, planting the orchard, the best time to plant trees, arrangement of trees in the orchard, cultivation of the orchard, irrigation of the orchard, pruning, thinning the fruit, fertilization of plums, and selection of varieties.

Varieties of the domestica group are principally planted in New Mexico. The American and Japanese groups do not succeed, on account of the late spring frosts, the almost certain occurrence of which is a determining factor in the selection of varieties. Descriptions are given of varieties that have fruited in the station orchard, together with tables showing the dates of blooming the last four years; and another table shows the maximum and minimum temperature during the blooming period. A number of varieties not in the station orchard are recommended for trial throughout the Territory.

Olive culture, Z. ESPEJO (*Cultivo del olivo. Madrid: M. G. Hernandez, 1898*, pp. 228).—In addition to treating of olive culture, notes are given of the insect and plant parasites and means for their repression.

The persimmon, J. C. WHITTEN (*Fruitman's Guide*, 7 (1899), No. 157, p. 14).—Notes on the variability, marketing, use, and propagation of this fruit.

Modern viticulture, G. DE DUBOR (*Viticulture moderne. Paris: Librairie Larousse, 1898*, pp. 156, figs. 100).—A popular work.

Summer irrigation of grapes, G. BARBA (*Prog. Agr. et Vit. (ed. L'est)*, 20 (1899), No. 2, pp. 46-54; 5, pp. 149-158, figs. 3; 7, pp. 202-207).—Winter and spring irrigation have long been practiced to destroy phylloxera. In this article the advantages of summer irrigation are discussed and methods and appliances are described.

Subwatering and dry air in greenhouses, J. C. ARTHUR (*Amer. Florist*, 14 (1899), No. 559, pp. 850-852, fig. 1; *Florists' Exchange*, 11 (1899), No. 7, pp. 166, 167).—The

essential features of what is believed to be at present the most perfect system of subwatering are presented.

Ornamental plants for Maine, W. M. MUNSON (*Maine Sta. Bul.* 46, pp. 8).—This is a popular bulletin, calling attention to the importance of ornamentation of rural homes. In determining what to plant, points to be considered are hardiness, season, habit, beauty of foliage, flower, and fruit. The use of native plants so far as possible is recommended, and a number of such are mentioned with the peculiar ornamental adaptabilities of each. For beauty of foliage the golden elder, the golden syringa, the purple berberry (*Spiraea thunbergii*), and stag-horn sumach are recommended. Among shrubs valuable for ornamental purposes on account of their fruit are mentioned the Tartarian honeysuckle, the strawberry bush (*Enonymus*), *Rosa rugosa*, snowberry (*Symphoricarpos*), high-bush cranberry (*Viburnum opulus*), black alder or winter berry (*Ilex verticillata*). Some of the ornamental trees that are adapted to the south central part of Maine are various species of the elm, maple, beech, chestnut, linden, birch, poplar, and oak. Among the most valuable shrubs are the spiraea, lilac, viburnum, and mock orange. Several plants of little or doubtful value are mentioned as such.

How to improve home grounds, J. C. BLAIR (*Gardening*, 7 (1899), No. 155, pp. 169-171).

The ornamental garden, L. J. TRONCET (*Le jardin d'agrément. Paris: Librairie Larousse*, 1898, pp. 180, figs. 150).—A popular work treating of floriculture in general. Descriptive and cultural notes on 750 species of cultivated flowers and shrubs are given. Many of the illustrations are lithographed in colors.

Grafting tea roses for forcing (*Florists' Exchange*, 11 (1899), No. 9, p. 226, figs. 3).—Methods of grafting, with explicit directions for manipulation.

Carnations; notes on recent introductions (*Florists' Exchange*, 11 (1899), No. 6, pp. 130-133, figs. 14).

Indoor grown carnations, C. W. JOHNSON (*Florists' Exchange*, 11 (1899), No. 7, p. 164; *Amer. Florist*, 14 (1899), No. 559, pp. 852, 853).—The author has obtained better results with carnations grown under glass the year round than by resorting to field culture in the summer months. His cultural methods are described.

Seedling chrysanthemums, F. A. WAUGH (*Garden*, 55 (1899), No. 1421, p. 96, figs. 2).—Notes on a collection of chrysanthemums grown from seed said to have come from Korea. The blooms, which were single, or nearly so, are described.

Crinum fimbriatum and its allies (*Garden*, 55 (1899), No. 1421, pp. 92, 93, pl. 1).—An enumeration of the cultivated species with horticultural notes.

Species of fuchsia (*Garden*, 55 (1899), No. 1420, pp. 74-76, pl. 1, figs. 7).—Botanical and horticultural notes.

Violet culture, W. L. MINOR (*Florists' Exchange*, 11 (1899), No. 6, p. 146).—Notes on the methods of a successful grower. A feature of the method is the sterilization of the soil, accomplished by distributing steam through common land tiles.

FORESTRY.

Report of the foreman of forestry, W. C. MACGOWN (*Canada Expt. Farms Rpt.* 1897, pp. 217-272, pl. 1).—A report is given by the foreman of forestry in which the present state of the forest belts at the central experimental farm is described, the progress of work in the arboretum, the planting of ornamental trees and shrubs, and lists of 100 of the hardiest and most ornamental species are given, together with a list of 100 of the best species and varieties of perennials for outdoor growing. Notes are also given on hedge planting with a list of hedge plants growing at the farm, and notes on the condition of and the work in connection

with the ornamental grounds. In connection with the forest belts the best results have been obtained with black walnut, white pine, European larch, white ash, Scotch pine, and canoe birch. Each of these species of trees seems to be adapted to certain conditions of soil cultivation or exposure.

The twenty-sixth convention of German Foresters (*Ztschr. Forst u. Jagdw.*, 31 (1899), No. 2, pp. 99-109).—Notes are given on the meeting of the German foresters held at Breslau, August 23-26, 1898.

Forestry in Minnesota, S. B. GREEN (*Minnesota Forestry Association*, 1898, pp. 31², pls. 60, figs. 47).—This handy little book was prepared specially for classes in forestry in the School of Agriculture of the University of Minnesota, and is an elaboration of lectures and notes which the author has used in teaching the elementary principles of forestry. The different subjects treated are embraced under the following heads: Trees and tree growth, forest influences, tree planting, forest management and rate of increase on trees; durability and fuel value of wood; propagation, nursery work, injuries to tree growth, and descriptions of the trees of Minnesota.

Tree planting in Nebraska, E. F. STEPHENS (*Forester*, 4 (1898), No. 12, pp. 250-252).—Some of the problems of tree planting in this State are mentioned and directions given for the proper planting of forests. The varieties of timber best adapted to the conditions of this region are discussed. The author thinks that it will be possible to make the growth of timber over the entire State entirely practicable.

The San Gabriel forest reservation, J. H. BARBER (*Forester*, 4 (1898), No. 12, pp. 240-244).—A brief description is given of this important forest reservation in southern California, and the different forms of arborescent vegetation are enumerated at some length. The principal shrubbery and aborescent vegetation of the cañons and mesas are described, and it is stated that the summits of the ranges are practically unbroken coniferous forests, the principal trees, in order of their numerical importance, being: *Pinus ponderosa*, *P. lambertiana*, *P. coulteri*, *Libocedrus decurrens*, and *Pseudotsuga macrocarpa*.

Forests in their relation to irrigation, H. MICHELSON (*Forester*, 5 (1899), No. 1, pp. 9, 10).—The results following the destruction of the forests in the Ebro and Volga valleys are reported and a comparison is drawn between the conditions now existing in Colorado and the above localities.

Growth of *Acacia mollissima* in California, J. B. DAVY (*Gard. Chron.*, 3, ser., 24 (1898), No. 606, p. 108).—A report is given of a spontaneous seedling of this tree which sprang up in the Botanical Gardens of the University of California in 1895. In the 3 years, without receiving any special care or cultivation, the tree attained a height of 31 ft. with a spread of 24 ft. The trunk was 6 in. in diameter 8 in. from the ground. It flowered sparingly for the first time in the spring of 1898.

Selection in forestry, A. CIESLAR (*Centbl. Gesam. Forstw. Wien*, 25 (1899), No. 2, pp. 49-74, figs. 8).—Experiments are reported with seedlings grown from seed of different origin.

Thinning of woods, J. NISBET (*Jour. Bd. Agr. [London]*, 5 (1898), No. 3, pp. 292-299).—The principles underlying proper forest thinning and directions for thinning various kinds of forest growth are given.

The destruction of seed of oaks and pines by *Gastropacha quercus*, ALTUM (*Ztschr. Forst u. Jagdw.*, 31 (1899), No. 1, pp. 35-44).—Notes the destruction of these seeds in the ground and suggests means for preventive measures.

Concerning the multiplicity of forms in *Picea excelsa*, C. SCHRÖTER (*Frlschr. Naturf. Gesell. Zurich*, 43 (1898), No. 2-3; abs. in *Centbl. Gesam. Forstw. Wien*, 25 (1899), No. 1, pp. 21-23).

DISEASES OF PLANTS.

The effect of aqueous solutions upon the germination of fungus spores, F. L. STEVENS (*Bot. Gaz.*, 26 (1898), No. 2, pp. 377-406, fig. 1).—The primary object of the investigations here reported was to ascertain with some degree of accuracy the strength of various solutions which are necessary to prevent fungus growths. The bearing of this question upon the relation of a fungicide to its efficiency is apparent, and it seems important to study the principles underlying their action. By means of the van Tieghem hanging drop, cultures were made of *Botrytis vulgaris*, *Macrosporium* sp. from the fruit of *Datura tatula*, *Glucosporium musarum*, *Uromyces caryophyllinus*, and *Penicillium crustaceum*. The methods of the experiments are fully described and the different chemicals used are enumerated. The solutions used were made by adding the molecular weight of the salt or acid taken in grams to 1 liter of water. In all more than 1,500 cultures were made, from which the author deduces the following conclusions: Mercuric chlorid is the strongest chemical used in its toxic effect upon fungi, while potassium cyanid is remarkably weak considering its great toxic action on animals. Various fungi offer different resistance to poisons, and the limits of resistance may vary in the same species. Alcohol and sodium chlorid seem to have a stimulating effect.

In general the results obtained accord with the theory of hydrolytic dissociation. A chemical may be twice as powerful as another against one fungus, but may act upon another in an entirely different ratio. The spores of fungi are much less susceptible than the roots of seedlings. Bordeaux mixture, as ordinarily formed, contains far more copper than would be necessary if dissociated into copper ions. The cations Hg, H, and Cu and the anions CN, CrO₄, Cr₂O₇, and OH are poisonous, while the halogen anions are not poisonous.

Uromyces offers the greatest range in its susceptibility to poisons. Secondary spores of anthracnoses increase in abundance under the adverse conditions of a toxic solution. Spores protected by actual contact with others may germinate and the tube grow in a solution which would have prevented the germination of the spore had it been in contact with it. Peculiar knotty or twisted hyphae frequently result from the attempt to grow in a poisonous solution. A spore may be able to germinate and grow slightly in a solution in which it is unable to attain its full development. Potassium permanganate at certain strengths acts as a selective stain, differentiating the uredo from the teleutospores of *Uromyces caryophyllinus*.

Bread may be moistened with a solution which will prevent the germination of the spores, but after evaporation of the solution the spores can then grow. An occasional spore may germinate and grow perfectly normally in a solution which prevents hundreds of normal spores around it from germinating. *Penicillium* in a nutrient medium offers

greater resistance to poisons than do any of the other fungi investigated. *Uromyces* does not diminish in vigor of growth with the increased strength of the poisons, but it does diminish in the percentage of spores which germinate.

Influence of wet weather upon parasitic fungi, B. D. HALSTED (*Proc. Amer. Assoc. Adv. Sci.*, 47 (1898), pp. 416).—The author states that there is apparently some connection between weather and the occurrence of parasitic fungi. During 1898 the month of May was remarkably wet and the following June brought an abundance of parasitic fungi. Among these were the rusts of hollyhock, cedar, and mandrake; smuts of lily, spring wheat, and oats, and peach leaf-curl fungus. It is stated that the year 1889 was noted for its wet summer and also for the destruction of potatoes by rot. In 1897 July was phenomenal for its heavy precipitation, 11.42 in. This was followed by a serious outbreak of potato rot, causing a wholesale destruction of the tubers. *Phytophthora phaseoli* was discovered in the wet summer of 1889 and reappeared destructively in 1897. The records of the New Jersey Station show that both the wet years mentioned were noted for the abundance of black rot of grapes and rust of apples. In 1894 the growing season opened with a wet May and closed with a rainy September. There were long periods of cloudy weather and often it was hot and showery. This year witnessed an unprecedented outbreak of fire blight of apple, quince, and pear. In 1896 there was a rainy June and July and during this period the asparagus rust made its appearance in the eastern United States to an alarming extent, and in 1897 it was even more abundant. "There are not sufficient data for safe and substantial generalizations, but heavy rainfalls in spring seem to induce rusts in grains and orchard and garden crops, and the fire blights of fruit trees. Midsummer precipitations favor the decay of fruits, particularly the stone fruits, and the rotting of potatoes. Rainfall does not express all the meteorological conditions that need to be taken into consideration in this connection."

Concerning the etiology of some diseases of cultivated plants, F. CARVARA (*Staz. Sper. Agr. Ital.*, 30 (1897), No. 6, pp. 482-507).—The author gives extended observations upon what he terms the tuberculosis of the grape, necrosis of grape stems and shoots, necrosis of mulberry, and tuberculosis of the peach. All these diseases are said to be of bacterial origin. The author claims to have isolated the organisms, cultivated them on artificial media, and produced the diseases by inoculation from cultures.

Tuberculosis of the grape is said to greatly resemble olive tuberculosis, but may be distinguished by the greater number of small tubercles. These tubercles form in groups under the periderm, causing protuberances, resulting in the breaking of the cortex. This takes place especially near the nodes bearing the bunches of grapes, and when the vine becomes old the branches are nearly surrounded by them. The affected

plants bear sickly looking leaves of a yellowish-green color. The nodes where the tubercles are formed are 2 or 3 times their normal size. The organism causing this disease is 1 to 2 μ in length, cylindrical, with rounded ends. It grows more rapidly upon gelatin than on agar. Comes is said to have identified the organism as *Bacterium gummi*, but the author considers it identical with *Bacillus ampelopsora*. The disease is thought to be propagated quite extensively through the roots, which were observed to bear numerous excrescences.

The necrosis of the grapevine is said to be the same disease as that called *mal nero*, or bacterial gummosis. It is characterized by the sickly appearance of the shoots of the present year's growth, which are also much shorter than healthy ones. They are of a yellowish color, with characteristic gangrenous black ulcers at the point of connection of the shoot with the vine proper. These ulcers are sometimes of a circular form, but more often extend in long narrow strips half the length of the internode. Accompanying these there is a depression or corrosion of the tissues, the woody fiber and even the pith being affected. The leaves become yellow and wither and the bunches of grapes are arrested in their development and completely dried up. The bacterial origin of this disease is said to be well established, and according to the author is *Bacillus vitivorus*. Cultivated on gelatin the bacillus is 1 to 2 μ in length. It possesses considerable vitality, since cultures remained alive all winter in the laboratory where the temperatures varied from 4 to 25° C. Six successful inoculation experiments with the organism are reported. Close pruning and sulphuring the bunches of grapes with equal parts of sulphur and lime, after which the vines are sprayed several times with Bordeaux mixture, is said to be efficient in arresting the disease.

Necrosis of mulberry trees has received considerable attention on account of its destructive nature. The author has isolated 2 bacteria, one of which is probably *Bacillus cuboniatus* and the other a new species to which the name *B. mori-carneus* is given. Both organisms have been cultivated on artificial media and their characteristics are described.

The peach tuberculosis is said to be caused by *Clostridium persici-tuberculosis*, a new species of bacteria, the characteristics of which are described at some length. The disease, which has occurred quite abundantly in the vicinity of Pavia, is characterized by the presence of tubercles upon the branches of 1 or 2 years' growth, but are rarely found on older ones. They are of globular or flattened globular form, 1 or 2 cm. in diameter. At first they appear as slight protuberances, corresponding ordinarily to the first appearance of a bud, and they cause the epidermis to be raised, constituting a sort of hyperplasm of the cortical parenchyma. The presence of these tubercles usually kills the branch, although it may survive until the second year. The tissues affected are not confined solely to the bark, but extend to the woody

cells, which become more or less transformed. This disease in the orchard examined was exceedingly abundant, and the small tumors were found on 30 out of 50 trees and in a few hours as many as 500 affected branches were cut out. The peach tuberclosis has frequently been confused with the bacterial gummosis of pomaceous fruits, but the author maintains that they are very distinct. It is said that by pruning the course of this disease may be arrested, although no experiments are reported where its efficiency has been tested.

Fungus diseases, J. CRAIG (*Canada Expt. Farms Rpt. 1897, pp. 110-120*).—Notes are given of a number of the more common parasitic diseases of cultivated plants, and experiments are reported on the effect of shading on the production of gooseberry mildew. The plants were shaded by planting hills of corn on the south, east, and west sides of the gooseberry plants. The results obtained seem to indicate that the shading reduced the amount of gooseberry mildew, and this experiment is to be repeated on a more extensive scale.

Attention is called to the attack of *Heterosporium gracile* on species of cultivated iris, and applications of Bordeaux mixture are recommended as a preventive treatment.

A dry rot of apples which is said to be caused by a fungus closely resembling *Penicillium glaucum* is briefly described.

A peach disease which has been observed for several years is described, the characteristics of it being abnormally thickened annual shoots; a marked increase in the buds; tufted broom-like growths involving a single twig or branch, or sometimes even the entire top of the tree, the color of the foliage being somewhat lighter green than normal and the leaves much narrower and contorted. The symptoms of this disease are somewhat like those of peach rosette, and specimens submitted to the Division of Vegetable Physiology and Pathology of this Department were identified as resembling rosette, but no positive opinion was given. On account of the serious nature of this disease the author recommends the cutting and burning of all affected trees.

A serious grape disease has been under observation for several years. The affected vine may be recognized by the leaves, which become light yellow in color; the canes are shortened and the tendrils often abortive. The root system is very imperfect. Microscopical examination of affected plants did not reveal any fungus, bacteria, or insect that could be positively identified as the cause of this disease. Assuming that the trouble may be due to a lack of nutrition, a series of experiments has been begun with different fertilizers and these will be continued for some time.

Experiments for the control of potato scab were conducted in which 2 varieties of potatoes were treated with various fungicides. The ones used were corrosive sublimate, kainit, nitrate of soda, potassium sulphid, sulphur, formalin, and lysol. The results obtained by these experiments showed that there was a marked difference in the 2 varieties in their susceptibility to the potato scab, one variety being affected

very little, while in the other 90 per cent of the tubers of the checked plat were affected by the scab. In these experiments the lysol solution gave the best results, followed by corrosive sublimate. The use of formalin gave very unsatisfactory results, quite at variance with the results of J. C. Arthur at the Indiana Station (E. S. R., 9, p. 456).

Brief notes are given of the injury done to roses by growth of *mucor*, and on the leaf spot of celery.

Experiments were also conducted with the fungus parasite of the San José scale, from which it appears that this parasite (*Spharophila coccophila*) can not be looked upon as a practical preventive of the scale in southern Ontario.

Experiments were conducted with corrosive sublimate, kainit, nitrate of soda, potassium sulphid, formalin, and lysol for the prevention of bean anthracnose. One and one-half per cent solutions of lysol gave satisfactory results, followed by formalin and potassium sulphid. If further trials of these fungicides should corroborate the results given, lysol would supersede copper sulphate as a preventive of bean anthracnose, as the results obtained are more satisfactory than those in former experiments with copper sulphate.

Rust in wheat during the dry season of 1897, D. MCALPINE (*Agr. Gaz. New South Wales*, 9 (1898), No. 12, pp. 1121, 1122).—Notes are given of a number of specimens of wheat that were submitted to the author to ascertain the presence of rust. The season had been an exceedingly dry one and was considered unfavorable for rust growth, but the specimens showed the presence of a few rust pustules and associated with them were 2 saprophytic fungi (*Cladosporium herbarum* and *Septoria glumarum*).

As bearing on Eriksson's hypothesis (E. S. R., 9, p. 118) of the existence of a symbiotic mycoplasma in wheats whereby the rust is carried from one crop to another, the author states that he grew seed of 10 varieties of wheat that had been sent him from Sweden by Eriksson and although they were all attacked by either one or both of the native species of rust, they were entirely free from the yellow rust (*Puccinia glumarum*), the rust which attacks wheats most severely in Sweden. This evidence, though not conclusive, on account of the fact that the variety of wheat was selected as one resistant to the yellow rust, seems to be somewhat opposed to the theory advanced by Eriksson.

The treatment of sooty mold (fumagine), L. DEGRULLY (*Prog. Agr. et Vit.*, 30 (1898), No. 52, pp. 749-751).—The author mentions various attempts to control this disease. Among the winter treatments recommended are spraying with kerosene emulsion and the use of sulphuric acid washes. It is stated that during the past season in Gironde a solution composed of water 100 liters, fat lime 20 kg., and crude petroleum 10 kg. was used. Another formula said to have been used with success was crude petroleum 5 kg., crude naphthaline 8 kg., quick lime 25 kg., and water 100 liters. The author believes that the absolute efficiency of these solutions has not yet been established, and has made arrangements to have them tested on a greater scale.

Notes on Stewart's sweet-corn germ (*Pseudomonas stewarti*), E. F. SMITH (*Proc. Amer. Assoc. Adv. Sci.*, 47 (1898), pp. 422-426).—The author reports having received from F. C. Stewart, of the New York State Station, in 1898 pure cultures of the organism, which had been described as the cause of a disease of sweet corn (*E. S. R.*, 9, p. 1056). He states that with some exceptions, as far as he has studied it the organism possesses the characters assigned to it by Stewart, and some others which will help to readily distinguish it. The behavior of the organism on various media is fully described. It seems to be an undescribed form, is motile by a single polar flagellum, and has been designated *Pseudomonas stewarti*, n. sp. The following synopsis of characters is given:

"A medium-sized rod rounded at the ends and motile by means of one polar flagellum, size 0.5 to 0.9 by 1 to 2 μ , no spores observed; found in enormous numbers in the vascular bundles of corn (*Zea mays*) associated with a destructive disease of which it is probably the cause; color in the host plant and in culture media yellow (buff to chrome or ochre, occasionally a pale, dirty yellow); aerobic and facultative anaerobic; grown in all ordinary culture media; bears alkali well (soda); and plant acids extremely well; grows luxuriantly in Uchinsky's solution; growth enormously stimulated by cane sugar, grape sugar, and galactose; growth not favored by 5 per cent doses of lactose, maltose, dextrin, mannite, or glycerin in nutrient starch jelly; diastatic action feeble, *i. e.*, able to obtain food from starch only with much difficulty; produces alkalis in all sorts of media and acids in the presence of grape and cane sugar; reduces litmus slowly; does not liquefy gelatin; does not liquefy Loeffler's blood serum; grows well at summer temperatures of 25 to 30° C.; does not die out quickly in culture media; does not produce gas; sensitive to light; occurs in New York and Michigan, and may be looked for in all parts of the United States."

The time for treatment of black rot in southeastern France, J. PERRAUD (*Compt. Rend. Acad. Sci. Paris*, 126 (1898), No. 19, pp. 1377-1379).—In a previous paper (*E. S. R.*, 9, p. 761) the author has shown in general the time of the different invasions of black-rot fungus in the vineyards of southeastern France. In the present paper he reviews experiments conducted in 1896 and 1897 for the prevention of this disease. In 1896, the times of the appearance of the black-rot fungus were May 26, June 10 and 22, July 5 and 18, and August 1 and 17; and sprayings were given the vines on the following dates: May 5 and 15, June 1, 13, and 25, and July 8, 18, and 30. In summarizing the results of the work in 1896, it is stated that 4 applications of fungicides, made May 15, June 1 and 25, and July 18, were sufficient to entirely protect the crop.

In 1897 the black rot appeared in the vineyards May 28, June 23, July 6 and 20, and August 4. The sprayings in this year were made on May 1, 12, and 20, June 2 and 26, July 3 and 17, and August 3. In this year, although the vineyard was injured by a heavy hailstorm, 98 per cent of the grapes were saved by treatments given the vines on May 12, June 2 and 26, and July 13; and the author states that the preservation would have been complete had there been a supplementary treatment July 3.

Generalizing from the experiments of the years 1896 and 1897, the

author states that 4 applications are all that are usually necessary, and these should be given the vines at times which coincide with certain easily distinguished periods of growth, namely, (1) when the young shoots are 15 to 20 cm. in length; (2) at the time when the flowers are beginning to open; (3) at the close of the flowering period, and (4) when the grapes have attained about one-half their full size. The most critical time in combating the black rot is stated to be the fortnight following flowering and the last half of July.

In conclusion, the author states that the 4 applications given as above will usually be found all that are necessary, but occasionally supplemental treatment will be necessary if a sudden attack of the fungus should be imminent.

The life history and characteristics of the pear-blight germ, M. B. WAITE (*Proc. Amer. Assoc. Adv. Sci.*, 17 (1898), pp. 127, 128).—The author states that the first appearance of the germs on the new growth of the season in the spring appears on the nectar disks. The bacilli live and multiply in the nectar and are able to infest the host without puncture or injury through the nectar glands. The distribution from flower to flower and tree to tree is through the agency of insects. Infection also occurs on young shoots and less frequently on the fleshy bark through injuries. No evidence has been found that the germs are carried by the wind. The blight germs usually die out in the twigs which are blighted, but in certain cases they manage to keep alive through the summer, making slow growth in the fleshy bark. Such cases may succeed in living over a winter, winter weather being favorable to the longevity on account of moisture and low temperature. These hold-over cases of blight are apparent in the spring by the exudation of considerable quantities of gummy matter full of bacilli. These are visited by insects, principally flies and wasps, which carry the germs to the newly opened flowers, thus completing the life cycle.

The characters of the bacillus are briefly given, its appearance when cultivated upon various media described, and certain statements formerly made which are now known to be erroneous are corrected. The color of the germ mass, which has previously been stated to be yellowish white on the potato, must have come, in the author's opinion, from impure cultures as the true pear-blight germ is always white. No gas is formed, contrary to previous expressions, and while the germ produces some acids, no butyric acid is produced in its decomposition. It has been stated that starch is decomposed and used as food by the germ in cultures, but in the author's experiments this has never been demonstrated. It has also been claimed that the germ lives over winter in the soil, but so far the author has failed to find any evidence of this fact.

Notes on some diseases of southern pines, H. VON SCHRENK (*Proc. Amer. Assoc. Adv. Sci.*, 17 (1898), p. 111).—Of the numerous parasitic fungi attacking the species of southern pines, *Trametes pini* is said

to be by far the most destructive. This fungus attacks the older trees, entering through a knot and causing disintegration of the heartwood. The mycelium dissolves portions of the wood fibers, at first changing them to cellulose. After a time the solution stops and the wood then appears full of holes with a white lining, the holes separated by lamellæ of comparatively sound wood. The wood not destroyed seems to be protected against the attacks of fungus ferments by some substance which infiltrates into the wood cells. The author thinks that in the case of pines attacked by this fungus, a compound allied to the humus compounds, is present which gives the wood a brown color.

Another fungus, *Trametes radiciperda*, enters the trees through the roots; the mycelium passes up into the trunk, causing decay similar to that described above. This disease has been found destroying numerous trees of *Pinus palustris* and *P. echinata*.

Plant diseases observed in Denmark during 1896, E. ROSTRUP (*Tidsskr. Landbr. Plantearl.*, 4 (1897); *abs. in Ztschr. Pflanzkrank.*, 8 (1898), No. 5, pp. 278-280).—Notes are given on the principal fungus and insect injuries to cereals, grasses, leguminous forage plants and garden crops.

Plant diseases appearing in Italy in the year 1897, G. BRISI (*Bol. Not. Agr.*, 19 (1897), pp. 124-133; *abs. in Ztschr. Pflanzkrank.*, 8 (1898), No. 5, pp. 273-277).—Notes are given on the more important fungus diseases observed during the period indicated.

Sensitiveness of certain parasites to the acid juices of the host plants, E. F. SMITH (*Bot. Gaz.*, 27 (1899), No. 2, pp. 124, 125).—In a brief abstract the author states that the comparatively slow progress of *Pseudomonas campestris*, *P. phaseoli*, and *P. hyacinthi* when inoculated into the host plants, even in enormous numbers, led to the belief that the restraining influence must be the acid juices of the cabbage, bean, and hyacinth. In studying these organisms all the fluids in which they were grown were tested, being titrated with caustic soda and phenolphthalein, so that the exact grade of acidity which retarded growth was definitely known. The full results of the author's experiments are promised in another paper.

The plant parasites of coffee, G. DELACROIX (*Rev. Cult. Coloniales*, 4 (1899), No. 21, pp. 34-38).—The parasites are said to be several species of Loranthus, an alga, *Cephaleuros coffea*, a number of Ascomycetes, and 2 species of Hemileia.

Concerning the symbiotic mycoplasmic theory in grain rusts, H. L. BOLLEY (*Centbl. Bakt. u. Par.*, 2. Abt., 4 (1898), No. 23, pp. 855-859; 24, pp. 887-897; 25, pp. 913-919, figs. 6).—This paper was presented to Section F of the American Association for the Advancement of Science at the Boston meeting August, 1898. An abstract of the paper is given in the proceedings of the Association (E. S. R., 10, p. 653). The author believes that Eriksson's theory (E. S. R., 9, p. 118) is not well founded, and that the infection is by the distribution of uredo spores by the winds.

Some important wheat diseases, C. O. TOWNSEND (*Maryland Sta. Bul.* 58, pp. 123-127).—Popular notes are given of the wheat smuts and rusts with suggested remedies. The author states that in certain parts of the State a *Septoria* (probably *S. glumarium*) is more or less prevalent.

Red rust of wheat, H. GARMAN (*Kentucky Sta. Bul.* 77, pp. 121, 122).—A brief popular summary is given of a paper presented by the author for a farmers' institute at Shelbyville, Kentucky, in which is summarized the present state of information relative to the cause of grain rusts.

The asparagus rust (*Bul. Soc. Cent. Hort. Seine-Inférieure*, 2. ser., 2 (1898), No. 5, pp. 361-363).—Notes the presence and injurious effects of *Puccinia asparagi* and

recommends spraying the beds with a solution of copper sulphate, 3 kg. to 100 liters of water.

On the relation of two species of *Puccinia* on *Stachys*, P. MAGNUS (*Ber. Deut. Bot. Gesell.*, 16 (1898), No. 10, pp. 377-385, pl. 13).—Notes are given on *Puccinia harioti* and *P. rossii*.

Diseases of carnations, P. SORAUER (*Ztschr. Pflanzenkrankh.*, 8 (1898), No. 5, pp. 283-295).—The author describes at some length 9 diseases of carnations that have been observed in Germany.

Root rot of alfalfa and sugar beets, V. PEGLIION (*Bol. Ent. Agri. e. Patol.*, 4 (1897), pp. 367-369; *abs. in Ztschr. Pflanzenkrankh.*, 8 (1898), No. 5, p. 300).—Brief notes are given on the attacks of *Rhizoctonia violacea* on the alfalfa roots and *Dematophora necatrix* on the beet roots.

The bacterial wet rot of potatoes, C. WEHMER (*Centbl. Bakt. u. Par.*, 2. Abt., 4 (1898), No. 13, pp. 540-546; 14, pp. 570-577; 15-16, pp. 627-637; 17-18, pp. 694-700; 19, pp. 734-739; 20, pp. 764-770; 21, pp. 795-805, pls. 2).

Combating potato diseases with Bordeaux mixture, E. GUTZEIT (*Fühling's Landw. Ztg.*, 48 (1899), No. 4, pp. 142-148).—Three varieties of potatoes were thoroughly sprayed with Bordeaux mixture and the results of the treatment are given. No *Phytophthora* appeared on the sprayed plants, and the yield of these plants as compared with the checks was as 161 to 100. There were more large potatoes and the specific weight and starch content were considerably higher, which was attributed to the fungicide.

A root disease of mulberry trees, N. ICHAKAWA (*Forstl. Naturw. Ztschr.*, 7 (1898), No. 12, pp. 423-428).—A disease of mulberry trees that has been known in Japan for at least 17 years is described. It is said to be caused by *Helicobasidium* sp. attacking the roots of the trees.

On the occurrence and prevention of grape diseases in Germany in 1896 (*Abs. in Ztschr. Pflanzenkrankh.*, 8 (1898), No. 5, pp. 307-310).—The diseases and injuries are classed under those induced by climatic influences, those due to insects, those caused by parasitic fungi, and those whose origin is unknown.

A bacteriological study of pear blight, LILLIAN SNYDER (*Proc. Amer. Assoc. Adv. Sci.*, 47 (1898), pp. 426, 427).—The author has made a study of the life history of the true pear-blight bacillus (*Micrococcus amyloporus*), but the principal part of the paper is taken up with the description of a second germ, which very frequently accompanies it. This germ was isolated and carried through various cultures and inoculation experiments made, and the author concludes that the second germ isolated from the tree in connection with the true blight is really saprophytic.

The leaves of the Red Astrachan apple immune from the attack of *Gymnosporangium macropus*, W. J. BEAL (*Proc. Amer. Assoc. Adv. Sci.*, 47 (1898), p. 421).—The author desiring to cultivate this fungus in the botanic gardens at the Michigan Agricultural College secured young cedars well supplied with living galls and planted them almost in contact with 2 young apple trees of the Red Astrachan variety. Artificial transfers were made of the spores from the cedar to the apple and numerous examinations made, but no traces of the fungus could be found on the apple leaves. The test was repeated in 1898 with similar results, and a letter from L. R. Jones, of the Vermont Experiment Station, is quoted, in which it is stated that he had tried to induce the telentospores of red cedar to attack red astrachans with negative results.

On the occurrence of a yeast form in the life cycle of the black rot of apples, W. B. ALWOOD (*Proc. Amer. Assoc. Adv. Sci.*, 47 (1898), p. 422).—The author reports the discovery of a yeast form in laboratory culture of the fungus causing the black rot of apple (*Sphaeria malorum*). This yeast form has been isolated and reinfections made on the fruit of apple produced the fruiting bodies characteristic of the black-rot fungus.

ENTOMOLOGY.

Report of the entomologist and botanist, J. FLETCHER (*Canada Expt. Farms Rpt. 1897, pp. 187-230, figs. 18*).—Notes are given on the jointworm (*Isosoma* sp.), the grain plant louse (*Siphonophora avenae*), and grasshoppers which affect cereals. The pea weevil (*Bruchus pisi*) and pea moth (*Semasia nigricana*) are described at some length and suggestions given for their destruction. Insects which attack root crops and vegetables are described. Among them are mentioned cut-worms, blister beetles, carrot rust fly (*Psila rosa*), and spinach carrion beetle (*Silpha bituberosa*). Insects affecting fruits are described, the more important of them being the tent caterpillar, cankerworms, shot borer (*Nycteborus dispar*), oyster-shell bark louse (*Mytilaspis pomorum*), apple maggot (*Trypeta pomonella*), apple fruit miner (*Argyresthia conjugella*), various species of plant lice, strawberry crown borer (*Tyloclerma forecolatum*), currant maggot (*Epochra canadensis*), native currant sawfly (*Gymnonyctus appendiculatus*), and the San José scale. The life history and notes on the attacks and methods of prevention are given for these different insects.

A report on the management of the apiary by J. Fixter is appended in which a chronological history of the bees during the season of 1897 is given. Experiments in wintering are also reported, in which 15 colonies were put into winter quarters in the cellar and placed on shelves beginning 18 in. from the floor. Under the back end of each hive was placed a 3-inch block by which each hive was raised so as to secure ventilation. These hives were put in the cellar with the tops and bottoms of the hives left on. Two colonies were stored in a root house, 2 were placed in a pit dug in the side of a hill, and 2 were wintered in a wood shed. The mode of wintering which gave the best satisfaction was the first. The other methods were more or less unsatisfactory, owing to a number of causes.

The report concludes with a brief account of the distribution and value of awnless brome grass in Canada.

Experiments with bees, S. A. BEDFORD (*Canada Expt. Farms Rpt. 1897, pp. 331, 335*).—An experiment is reported in wintering bees in which the hives were placed 6 in. from the floor and protected with a piece of old woolen carpet placed under the wooden cover. When placed in the cellar each colony had 30 lbs. of honey, which proved more than sufficient for the winter, and all the hives wintered successfully. The temperature of the cellar, as shown by a self-registering thermometer, remained steadily between 40 and 50° F.

In 1896 some difficulty was experienced with persistent swarming of the bees, resulting in the weakening of the colonies, and in the following year most of the brood frames were filled with bees and a large upper story filled with wire foundations was added and the frames extracted as required. This gave an abundance of room and no swarming whatever occurred and all the colonies became strong before fall. An average of 45 lbs. of extracted honey was taken from each hive.

A list of plants which are visited by bees is given, arranged in the order of flowering.

Miscellaneous injurious insects, C. V. PIPER and R. W. DOANE (*Washington Sta. Bul. 35, pp. 21, figs. 13*).—On account of the rapidity with which the San José scale has spread over the State and the great amount of damage it is causing, the authors have given descriptive notes and an account of the life history of this insect. The most approved remedies for the destruction and prevention of the distribution of the scale are given.

The bud moth (*Timlocera ocellana*), which was unknown within the State 3 years ago, is now reported as having gained a foothold in several sections and has done much damage wherever noted. The appearance of the insect at different stages of development is described. The remedies suggested for combating it are spraying trees with Paris green during the early stages of the larvæ, or just as the larvæ are leaving winter quarters and beginning to eat their way into the buds. On account of the peculiar habits of this insect these are about the only periods at which it can be successfully treated.

The strawberry crown moth (*Sesia rutilans*) is figured, its habits and life history described, and remedies suggested. The best, surest, and easiest way to control this pest, the authors state, is to watch the plants early in the spring and dig out and destroy by burning any dead and dying plants, or any that from weak condition seem to indicate that they may be infested.

The plum sphinx (*Sphinx albescens*) is figured and described. When abundant the trees should be sprayed with Paris green for the prevention of injury. Hand picking, however, will ordinarily be sufficient to keep these insects in check. The sphinx is parasitized by a small wasp-like insect (*Rhogas fumipennis*).

Illustrated notes are given on the tomato worm and blister beetles, with suggested remedies.

The strawberry thrips and the onion thrips, A. L. QUAINANCE (*Florida Sta. Bul. 46, pp. 77-111, figs. 12*).—The author reports the occurrence of *Thrips tritici* during the spring seasons of 1895 and 1897, when it proved quite destructive to strawberries and other crops. The insect is said to be present in Florida throughout most of the year, but it was only during March, April, and May in the 2 seasons indicated that serious damage was done. In both these seasons the strawberry crop of Florida was reduced fully one-third by the action of these insects. The thrips attacks the pistils of the strawberry most frequently, resulting in the blighting of the ovaries. In addition to the attacks on the pistils, the petals, particularly at their bases, and also the stamens are attacked to some extent. The injurious effect of these insects seemed to be in preventing the fertilization of the ovules. Since the stigmas are attacked, the normal fertilization is greatly retarded, if not entirely prevented.

In March, 1898, the thrips was very abundant about Lake City and

in April attacked the foliage of various plants, such as Le Conte pears, Kelsey plums, English peas, parsley, and endive. The damage to the flowers of the strawberry was not so severe as in 1897, but blackberries, dewberries, and roses suffered considerably more.

The life history and habits of the insect were studied, from which it appears that the life cycle of *Thrips tritici* is quite short, requiring but 12 days. The eggs are deposited in the tissues of the infested plants and hatch in 3 days. The larval stage lasts about 5 days, during which time the insect makes 2 molts. The nymph stage continues for about 4 days, in which time no food is taken.

In 1897-98 experiments were conducted with a number of insecticides for the control of this pest, and while a number of them proved valuable, the laboratory experiments showed that rose-leaf insecticide, whale-oil soap, kerosene emulsion, pyrethrum powder, and Hammond's thrips juice were all efficient in destroying the insect under laboratory conditions. For field purposes the most successful insecticides are rose-leaf insecticide, whale-oil soap, and kerosene emulsion, but on such fruits as the strawberry, blackberry, etc., the author recommends the use of the rose-leaf insecticide, since the oils present in the other 2 give a disagreeable flavor to the fruit.

During the spring seasons of 1897 and 1898 *Thrips tabaci* has proved very destructive to onions, cauliflower, and cabbage in the vicinity of Lake City. These insects were first noted about the middle of April, when they were observed to be infesting onions in the station gardens, and continued their destruction until about July 1, when they gradually disappeared. This species is injurious to the foliage of many plants. On onions it chafes the epidermis of the green leaves, causing them to dry out, whiten, and frequently die. On cabbage and cauliflower the effects are about the same. The life history and habits of this insect show that it has a somewhat longer life cycle than that of *T. tritici*, requiring about 16 days for its completion. This insect goes through 3 molts during its life cycle. The egg state lasts about 4 days, the larval stage 8 days, and the nymph stage 4 days.

This species of thrips can be successfully combated by the use of the same insecticides as recommended for the previous species except that the solutions should be somewhat stronger.

Report on the San José scale in Maryland and remedies for its suppression and control, W. G. JOHNSON (*Maryland Sta. Bul.* 57, pp. 116, figs. 23).—Preliminary to a discussion of the San José scale, the author reviews the entomological work of 1896 and 1897 and gives an extended account of the introduction, present condition, distribution, and life history of the San José scale. The operations conducted in Maryland for destroying the insect and preventing its further introduction are given at considerable length. Fumigation with hydrocyanic-acid gas is considered the most successful treatment. Experiments with whale-oil and other kinds of soap and kerosene are reported upon and the result of their application in Maryland is stated.

Insects injurious to currants and gooseberries, C. V. PIPER and R. W. DOANE (*Washington Sta. Bul. 36, pp. 16, figs. 81*).—The authors state that there are at least 3 different species of insect in the State which attack and destroy the fruit of the currant and gooseberry. These insects are the dark currant fly (*Rhagoletis ribicola*), yellow currant fly (*Epochra canadensis*), and gooseberry fruit worm (*Dakrma convolutella*). The insects are fully described and their habits and life histories given and various remedies suggested for their prevention. Illustrated notes and life histories are also given of the following insects which are injurious to the foliage of the currant and gooseberry: Native currant sawfly (*Gymnomychus appendiculatus*), pepper-and-salt currant moth (*Eubyia cogitata*), currant aphid (*Myzus ribis*), currant borer (*Sesia tipuliformis*), and western pulvinaria (*Pulvinaria innumabilis occidentalis*).

Notes on horntails and their host plants, W. LEISEWITZ (*Ztschr. Forst Naturw., 7 (1898), No. 12, pp. 139-142*).—The author enumerates a number of species of horntails, arranging them according to the woody plants upon which they live. The species are as follows:

Spruce—*Sirex gigas*, *S. spectrum*, *S. juvenis*, *S. noctilio*, *Xiphydria camelus*: pine—*Sirex gigas*, *S. juvenis*, *S. noctilio*, *Xiphydria camelus*: Abies—*Sirex gigas*, *S. spectrum*, *S. juvenis*, *Xiphydria camelus*: larch—*Sirex gigas*: oak—*Sirex magus*, *Xiphydria longicollis*, *Cephus cynosbati*: beech—*Cephus cynosbati*, *Sirex magus*, *S. fuscicornis*: maple—*Sirex magus*, *Xiphydria longicollis*: elm—*Xiphydria* sp., *X. dromedarius*: birch—*Sirex magus*, *S. fuscicornis*, *Xiphydria longicollis*, *X. camelus*: alder—*Xiphydria camelus*, *Oryssus respertilio*: poplar—*Sirex fuscicornis*, *Xiphydria dromedarius*: willow—*Xiphydria dromedarius*, *Cephus cynosbati*: pear—*Sirex magus*, *Xiphydria longicollis*, *Cephus abdominalis*, *C. compressus*: Rubus—*Cephus fumipennis*: and Spiraea—*Cephus major*.

A spraying mixture for cauliflower and cabbage worms, F. A. SIRRINE (*New York State Sta. Bul. 111, pp. 26-47, pls. 6*).—The use of a resin-lime mixture for the prevention of injury caused by the imported cabbage worm (*Pieris rapa*) and the cabbage looper (*Plusia brassicae*) is recommended. The formula for the insecticide is pulverized resin 5 lbs., concentrated lye 1 lb., fish oil 1 pt., and water 5 gal. This is to be made into a stock solution by placing the oil, resin, and 1 gal. of hot water in an iron kettle and heating it until the resin is softened, after which the concentrated lye is carefully added and the mixture thoroughly stirred. Four more gallons of hot water are added and the whole mass boiled until the mixture will unite with cold water, making a clear, amber colored liquid. When through boiling this mixture should make 5 gal. of the stock solution. When used the insecticide is prepared by combining 1 gal. of the stock solution, 16 gal. of water, 3 gal. milk of lime, and $\frac{1}{4}$ lb. Paris green. The water, resin, and milk of lime are combined, after which the Paris green is added. If the milk of lime should be added to the undiluted resin mixture, a heavy precipitate would be formed, which not only settles rapidly but interferes with spraying, as it clogs the nozzles.

This resin-lime mixture with Paris green was first tested in 1895, on elm trees for the elm-leaf beetle. Later it was used to spray ruta-bagas

which were badly infested with cabbage worms, and 3 days after treatment not a single living worm could be found. In 1896 and subsequently it was extensively tested on cabbage, cauliflower, and Brussels sprouts, and in every case when properly applied gave good results. During the fall and winter of 1897-98 it was tested on lettuce grown in forcing houses with good results, but the author does not recommend it for this purpose, as he thinks that the adults could be kept out of forcing houses by the use of mosquito netting to better advantage.

The experiments, which have been conducted on a considerable scale, indicate that the cost per acre of material and labor for 2 applications of this fungicide to cabbage or cauliflower would be about \$2. Power spraying pumps can not be used for spraying cabbage or cauliflower, owing to the method of growth.

The life history of the 2 most serious insect pests to cabbage and cauliflower growing is given and detailed recommendations made for the application of the insecticides. The use of arsenites on such crops as these is attended with some danger, but the author states that if the directions given are carefully followed no ill effects will result. It is explicitly stated that this mixture should not be used on cabbage after the heads are two-thirds formed; that only skillful and intelligent laborers should be trusted with the application of it on cauliflowers, and that it should never be applied after the "flower" has commenced to form. For the heading varieties of lettuce it can be safely used until the plants are one-third grown; to other varieties it should never be applied.

Spraying. J. CRAIG (*Canada Expt. Farms Rpt.*, 1897, pp. 105-110).—The apple orchards on the Central Experimental Farm were sprayed 4 times with Bordeaux mixture, and Paris green, and as a result of this work it was difficult at harvest time to find an imperfect specimen of fruit. Comparisons were made of using lysol and formalin in different strengths, the results indicating that lysol does not possess qualities superior or equal to any of the present standard insecticides. With formalin some deterrent influence against the codling moth was noted, but it is hardly equal as an insecticide to some of the arsenites. A comparison was made of Bordeaux mixture containing Paris green and of Paris green in water. In reporting the experiments the author states that it will not pay a fruit grower to incur the expense involved in making a separate application of Paris green in view of the very doubtful benefits derived. Different formulas of Bordeaux mixture were compared, the one containing 6 lbs. copper sulphate and the other 4 lbs., and when applied to crab apple trees the weaker solution was found to be equally as efficient as the stronger, and did not injure the foliage. Experiments with arsenate of lead, which were continued from the previous year, indicate that this is a very effective remedy against the codling moth. Arsenate of lead in combination with Bordeaux mixture was sprayed on a number of crab apple trees with disastrous results, seeming to indicate that this combination is injurious to both foliage and fruit.

Experiments are reported in which different fungicides were employed

to prevent peach-leaf curl, peach and plum rot, and the orange rust of the quince. Different strengths of lysol, copper sulphate, and Bordeaux mixture were employed. The lysol was apparently without much effect. The trees which were sprayed with copper sulphate developed peach yellows, and were destroyed before harvest, while the Bordeaux mixture proved very efficient in preventing the leaf curl. Bordeaux mixture made from 3 lbs. copper sulphate and 3 lbs. of lime to 1 barrel of water is recommended for application on peach and plum trees.

During the summer of 1897 plum, cherry, and apple trees were severely attacked throughout Ontario and Quebec by aphides, nursery stock and young orchard trees suffering the most. Experiments were conducted with kerosene emulsion, tobacco water, tobacco water and lemon oil, quassia chips and whale-oil soap for the destruction of these insects, and it was found that where cheapness and efficiency is considered, tobacco water with whale-oil soap produced the best results. Tobacco water and lemon oil gave the most decisive results, but the addition of lemon oil increases the cost of the solution. In spraying for the destruction of these insects care must be exercised that the liquid shall reach the under surface of the leaves, and 2 or 3 applications at intervals of a few days should be made in order to destroy the different generations of the aphides.

Modern apiculture, A. L. CLÉMENT (*L'apiculture moderne. Paris: Librairie Lounrouse, 1898, pp. 149, figs. 146, map 1*).—This is the fourth and revised edition of this work.

On the properties of cocoons of the various silkworm races of Japan, J. KAWARA (*Imp. Univ. Col. Agr. [Tokyo] Bul., Vol. 3, No. 5, pp. 508-520*).—Notes are given of the physical properties of the cocoons of 12 Japanese, 1 Chinese, and 1 Italian race of silkworms.

Notes on the insects of the year, F. L. HARVEY (*Maine Sta. Rpt. 1897, pp. 17-178, pl. 1*).—Brief notes are given on a number of insects. Among the more common which are of economic importance are the zebra caterpillar (*Mamestra picta*), the potato-stalk borer (*Gortyna nitela*), the apple-tree tent caterpillar, forest tent caterpillar, beech-bud insect, brown-tail moth (*Euproctis chryssorrhæa*), and a timber beetle (*Dendroctonus rufipennis*).

The enemies of agriculture, C. RAMON (*Les ennemis de l'agriculture. Paris and Nancy: Berger-Levrault & Cie., 1898, pp. 408, figs. 140*).—This work treats of injurious insects, fungus diseases, and injurious plants.

Insect and fungus diseases of fruit trees, and their remedies, ALLEN, BLUNNO, FROGGATT, and GUTHRIE (*Agr. Gaz. New South Wales, 9 (1898), No. 12, pp. 1426-1430, pl. 1*).—The life history and descriptive notes of 12 insect pests of the grapevine are given.

Injurious insects of the pear, V. MAYET (*Prog. Agr. et Vit. (ed. L'est), 20 (1899), No. 7, pp. 212-215*).—Notes are given on *Rhyrchites bacchus* and *R. coruleus conicus*, together with suggested methods for combating them.

Some notes on the entomology of Prunus, T. D. A. COCKERELL (*New Mexico Sta. Bul. 27, pp. 132-134*).—The important agency of wild bees in the cross fertilization of plums is pointed out. Attention is called to 3 insects infesting the wild cherry (*Prunus capollin*) in that region, namely, *Anthonomus (Tachypterus) quadrigibbus*, *Clisiocampa fragilis* var., and *Coleophora* sp., and the public is cautioned against their threatened introduction into orchards.

Combating cabbage pests, F. H. HALL and F. A. SIERINE (*New York State Sta. Bul. 144, popular ed., pp. 8, pls. 2*).—This is a popular edition of Bulletin 144 of the station (E. S. R., 10, p. 869).

Insect injurious to rosaceous plants, E. LUCET (*Bul. Soc. Cent. Hort. Seine-Inférieure, 2. ser., 2 (1898), No. 5, pp. 321-359, pls. 1*).—The present paper treats principally of scabrids and cecidios.

New genera and species of Australian Coleoptera, T. BLACKBURN (*Trans. Roy. Soc. South Australia, 22 (1898), No. 2, pp. 221-233*).

Notes on Australian Lepidoptera, A. J. TURNER (*Trans. Roy. Soc. South Australia, 22 (1898), No. 2, pp. 90-100, pl. 1*).

Descriptions of new Microlepidoptera, A. J. TURNER (*Trans. Roy. Soc. South Australia, 22 (1898), No. 2, pp. 200-214*).

The Hessian fly, W. G. JOHNSON (*Maryland Sta. Bul. 58, pp. 111-122, fig. 1*).—A brief popular account is given of the Hessian fly, its distribution throughout the State, and the best means for its suppression and control.

The ravages of *Bombyx pini* in Siedlec, Russian Poland (*Gesterr. Forst. u. Jagdw. Ztg., 17 (1899), No. 6, p. 43, figs. 2*).

Recent investigations of the European scale insects in comparison with the San José scale, FRANK (*Gartenflora, 48 (1899), No. 3, pp. 57-66*).

Experiments in combating *Cochylis ambiguella*, A. BATTAGLINI (*Bol. Ent. Agr. e Patol., 5 (1898), Nos. 1, 3, 4, 5; abs. in Ztschr. Pflanzenkrankh., 8 (1898), No. 5, pp. 311, 312*).—Experiments with finely powdered sulphur and 2 per cent rubin, and with preparation made of Bordeaux mixture and rubin, are reported. In addition to having valuable insecticidal properties, they also reduced the amount of mildew present.

Experiments in combating *Cochylis ambiguella*, A. BERLESE (*Bol. Ent. Agr. e Patol., 5 (1898), pp. 51-53; abs. in Ztschr. Pflanzenkrankh., 8 (1898), No. 5, p. 312*).—The author reports favorably upon what is known as Martini's mixture for the suppression of this insect. This mixture is composed of Bordeaux mixture and rubin and has an important fungicidal action. Soap emulsions were found to be valueless in combating this insect.

FOODS—ANIMAL PRODUCTION.

Food and food adulterants, H. W. WILEY ET AL (*U. S. Dept. Agr., Division of Chemistry Bul. 13, pt. IX, pp. VII + 1169-1374, pls. 7, figs. 1*).—This bulletin is an extended treatise on cereal grains and the products made from them. The composition of different grains and their various constituents are discussed on the basis of bulletins 9 and 45 of the division. The various constituents of different grains are spoken of in detail as well as methods of preparing cereals for food and the method of making and baking bread. The work of many investigators on the insoluble carbohydrates of wheat is cited, and investigations conducted by the Division of Chemistry are reported. Following are some of the chief results:

"As determined by the analysis of the osazones, only the pentoses, xylose, and arabinose result from the hydrolysis of the hemicellulose. This is, therefore, practically identical with the free or normal pentosans which the wheat contains.

"The preparation of cellulose from the fiber insoluble in dilute acid was found to be best effected by means of alkali and chlorine as described by Cross and Bevan. . . .

"The cellulose obtained as just mentioned, or by fusion of the fiber with strong alkali (Lange's method), contains furfuraldehyde-yielding bodies whose deportment toward reagents indicates the presence of penta-anhydrid, probably in combination with a part of the hexa-anhydrid or normal cellulose. When dissolved in sulphuric acid, diluted, and hydrolyzed, a small quantity of dextrose only was obtained as osazone.

"The property of dyeing in a solution of ferric chlorid and potassium ferricyanid is possessed in a marked degree by the wheat fiber, and the reaction has been found

useful in testing the purity of "cellulose" residues. In this respect, as in the formation of the lignone chlorid, the lignified tissue of wheat resembles that of jute, the typical lignocellulose.

"No notable amount of oxycellulose has been found in any of the preparations from the wheat fiber. . . .

"The digestibility of the components in a case where wheat bran had been fed alone was found to be: Starch, 100 per cent; free pentosans, 66.2 per cent; lignin and allied substances, 36.7 per cent; cellulose, 21.8 per cent.

"From the analyses given in this paper and the best available results of other experimenters, the proportions present in normal mature wheat, air-dried, are calculated as follows:

Average percentages of insoluble carbohydrates in air-dried wheat.

	Per cent.
Starch.....	51.0 to 59.0
Free pentosans.....	3.5 to 4.5
Lignin and its allies.....	2.0 to 2.5
Cellulose.....	1.6 to 2.1
Total insoluble carbohydrates.....	61.1 to 68.1

Investigations on the soluble carbohydrates are also quoted and work of the Division reported. The quantities of invert sugar, sucrose, and dextrin found are shown in the following table:

Invert sugar, sucrose, and dextrin or galactin in cereals and cereal products.

Name.	Invert sugar.	Sucrose.	Dextrin.
	Per cent.	Per cent.	Per cent.

The importance of the different mineral constituents in nutrition is discussed at considerable length.

Analyses are reported of a large number of samples of flour and of the various milling products of wheat, of patent, self-raising, gluten, and Indian-corn flour, rye, and buckwheat. The method of determining the heat of combustion of cereals is discussed at length, and a number of investigations reported comparing the values obtained by combustion of the constituents of cereals with the results obtained by calculation, using the ordinary factors. The following factors are proposed for the different carbohydrates and protein of cereals: Pentosans 3,800 calories per gram, cellulose 4,200 calories, sugar 3,950 calories, and protein 5,900 calories. Determinations of the oils of cereals gave the following values: Wheat oil 9,359 calories, rye oil 9,322 calories, Indian-corn oil 9,280 calories. The ether extracts of different cereals gave the following values per gram: Wheat 9,070 calories, oats 8,927 calories, barley 9,070, rye 9,196. The factor proposed for the calculation of the heat of combustion of fat of cereals is 9,300 calories per gram. On the basis of a number of actual determinations the heat of combustion, as calculated by these factors and as actually determined, is compared.

"While the variations in individual instances are considerable, the factors which have been adopted must be very nearly correct, inasmuch as the mean calculated calories differ very little from those determined by actual combustion. . . .

"In the light of the data here presented, we can with reason claim that the determination of the calorific power by combustion under pressure in oxygen is destined to be a valuable aid to the analyst in serving as a check upon the analytical data. We are further warranted in believing that whenever the calculated calories and the analytical data in hulled cereals and cereal products differ by as much as 100 from those obtained by combustion, the chemist will do well to repeat both the analysis and the combustion in order to discover the source of error. The calorimeter in this way becomes a valuable adjunct to the chemist in his work from a purely analytical point of view."

The average composition of different sorts of wheat and other flours is given, including entire wheat flour, self-raising flour, gluten flour, and flours made from corn, rye, and barley.

The carbohydrates in a number of flours are as follows:

Carbohydrates in flours.

	Sucrose.	Dextrin, galactin, and soluble starch.	Pento- sans and reducing sugars.	Crude fiber.	Starch (proteid factor, 5.70).
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Patent flours	0.10	0.20	Trace.	0.20	75.60
Common market wheat flours25	.20	0.01	.30	75.80
Bakers' and family flours10	.15	Trace.	.25	75.65

A number of adulterants in flour, meal, and bread are described, together with methods of deduction. A large number of analyses were made of bread purchased in Washington, D. C., breakfast foods and similar products, biscuits, crackers, cookies, and similar goods. The average results for different classes of bread are given in the following table:

Average composition of breads purchased in the open market.

Class.		In the original substance.										Heat of combustion (determined).
		Moisture.	Proteids (N 6.25).	Proteids (N 5.70).	Ether extract.	Carbohydrates excluded fiber, a	Crude fiber.	Ash.	Fat.	Digestible amino acids.	Heat of combustion (calculated).	
1	Vienna bread	38.71	8.87	8.09	1.06	53.72	0.62	1.19	0.57	89.87	4.455	4.458

The analytical data in the bulletin are discussed in detail, and much American and foreign work on the topics treated is summarized.

Forage plants and fodders, F. T. SHUTT (*Canada Expt. Farms Rpt.* 1897, pp. 146-151).—The composition is reported of awnless brome grass (*Bromus inermis*) ready for cutting; awnless brome grass hay, cut when the seed was just formed; when the seed was ripe; the straw from awnless brome grass hay and chaff (containing some seeds) from awnless brome grass; storksbill or alfilaria (*Erodium cicutarium*), green material and air-dried hay; "heavy feed" and buckwheat bran. "Heavy feed" examined under the microscope was found to consist chiefly of ground wheat and oats, the bran forming approximately 25 per cent of the whole. Storksbill hay had the following percentage composition: Water 10.32, protein 23.12, ether extract 4.53, carbohydrates 30.70, crude fiber 10.97, and ash 20.36.

On the absorption of several kinds of fat in the intestinal tract of man, N. KIENZL (*Oesterr. Chem. Ztg.*, 1 (1898), No. 6, pp. 198-202).—Experiments were made with a man 30 years old, weighing 78 kg., on the digestibility of butter, rendered butter, lard, oleomargarin, "margarin schmalz," and "margarin butter." "Margarin schmalz" is described as a mixture of oleomargarin with sesame and peanut oils, and margarin butter as a mixture of oleomargarin, sesame, and peanut oil with butter. The experiment was divided into periods of 2 days each. The feces were separated with charcoal. The butter and other fats used were analyzed and the fat in the feces determined. The results of the experiment are shown in the table below. In addition to the foods enumerated, soup and some vegetables were also consumed each day.

Digestibility of various fats by man.

Food per day.	Fat.			Coefficient of digestibility.
	In food.	In feces.	Digested.	
Period 1: Meat 243.5 gm., bread 425 gm., margarin butter 100 gm., and "margarin schmalz" 112.5 gm.	<i>Grams.</i> 291.8	<i>Grams.</i> 8.8	<i>Grams.</i> 193.0	<i>Per cent.</i> 95.64
Period 2: Meat 249.5 gm., bread 400 gm., butter 103.9 gm., and lard 138 gm.	225.5	6.6	218.9	97.07
Period 3: Meat 247 gm., bread 400 gm., margarin butter 103 gm., and oleomargarin 86.9 gm.	197.1	7.7	189.4	95.72
Period 4: Meat 250 gm., bread 343.5 gm., butter 130.4 gm., and rendered butter 72 gm.	183.0	6.2	176.8	96.65

Although the differences in digestibility of the various sorts of fat are small, the author does not believe that they are entirely due to experimental errors. The butter and lard and the butter and rendered butter are regarded as slightly more digestible than the other fats. The superior quality of the oleomargarin and similar products used is noted. The article contains references to previous experiments along similar lines.

The theory of fat resorption, III, O. FRANK (*Ztschr. Biol.*, 36, No. 4, pp. 568-593).—In continuation of previous work¹ the author reports a number of experiments with dogs. The principal conclusions were as follows: With the exception of stearic acid ester, ethyl esters of the higher fatty acids were consumed in large amounts by a dog. Before being resorbed they underwent cleavage in the small intestine. None was found in the chyle. From investigation it seems certain that a synthesis of fatty acids and glycerin to triglycerid takes place before fat is absorbed. In addition to the resorbed fats in the chyle, fatty material is also found which is derived from the intestine and intestinal juices. The secretion of such material is small—not greater than in the case of fasting.

Chemical composition of the carcasses of pigs, H. W. WILEY ET AL (*U. S. Dept. Agr., Division of Chemistry Bul.* 53, pp. 80).—A detailed study was made of the chemical composition of the carcasses of Berkshire, Tamworth, Chester White, Poland China, Duroc Jersey, and Yorkshire pigs. There were 3 Duroc Jerseys and 1 of each of the other breeds. The carcasses were received from the Iowa Station, and this investigation supplements a feeding test at the station not yet reported, comparing the different breeds. In addition to the regular cuts, the skin, bones, marrow, spinal cord, tendons, and hoofs were analyzed, the determinations made being water, fat, proteids insoluble in hot water, gelatinoids, flesh bases, lecithin, and ash. The results are reported in detail for each cut of each pig. The table which follows shows the composition of some of the more important cuts from each breed.

a In extracted sample.*b* Calculated from averages of like cuts.*c* In residue and fat extract.

The average composition of the meat from all cuts of the dressed carcass, the bones, marrow, etc., is shown in the following table:

Average composition of carcasses of pigs.

	Nitrogenous substances.					Fat.	Leci- thin.	Ash.	Total.
	Water.	Pro- teids in- soluble in hot water.	Gelati- noids.	Flesh bases.	Total.				
Meat from all cuts	<i>Per ct.</i> 35.85	<i>Per ct.</i> 7.20	<i>Per ct.</i> 0.72	<i>Per ct.</i> 0.96	<i>Per ct.</i> 8.88	<i>Per ct.</i> 53.51	<i>Per ct.</i> 0.23	<i>Per ct.</i> 0.54	<i>Per ct.</i> 98.99
Dressed carcass (with head, leaf lard, and kid- neys removed)	36.43	8.12	1.10	1.14	10.46	49.67	.23	2.11	98.90
Bones	38.55	18.03	.79	1.14	19.95	14.01	.31	25.44	98.26
Marrow	14.57	2.10	.14	.06	2.29	81.13	.13	98.11
Skin	46.33	13.09	8.67	4.59	26.35	22.89	.19	.62	96.52
Spinal cord	48.27	5.61	.86	.29	6.77	41.21	1.54	.39	97.94
Tendons	59.05	23.97	4.35	1.10	29.41	11.15	.19	1.07	100.87
Hoofs	43.8267	55.85	.88	100.77

The relative proportion of the different parts of the carcass to the entire dressed animal, weighing on an average, 144.6 pounds (the head, leaf lard and kidneys being removed), was as follows: Meat (fat and lean), 88.62 per cent; bones (less marrow), 6.28 per cent; skin, 4.67 per cent; marrow, 0.12 per cent; spinal cord, 0.08 per cent; tendons, 0.16 per cent, and hoofs, 0.08 per cent.

The analytical data are discussed in detail.

"In regard to the details of the various constituents, it is seen that the Berkshire leads all the others in the percentage of water, namely, 63.10. The smallest percentage of water is in one of the Duroc Jerseys, namely, 30.31. The largest percentage of fat is found in a Duroc Jersey, namely, 57.68, and the smallest in the Berkshire, namely, 40.46. Of the total nitrogenous substances, the largest quantity is found in the Berkshire, namely, 13.02, and the smallest in a Duroc Jersey, namely, 8.96. It is evident that the meat of the Berkshire is better for the production of muscular strength, while that of the Duroc Jersey is best suited for the production of animal heat. These remarks are made without any expression of opinion concerning the type as a whole, but only on the data obtained from the 2 animals. The examination of a large number of typical animals of each of the breeds would be necessary to establish a definite rule of that kind. It is fair to presume, however, that the single animal is to a certain extent typical, and therefore represents to that extent racial characteristics."

Digestion experiments, J. M. BARTLETT (*Maine Sta. Rpt. 1897, pp. 141-158, pls. 1*).—Experiments to determine the digestibility of mixed silage from mature flint corn, sunflower heads, and horse beans; corn, sunflowers (whole plant), and horse beans; Sanford corn; hay, mostly timothy; corn meal, and skimmed milk, were made with 3 sheep. The usual methods were followed. The feeding periods were of 12 days' duration, the first 7 days being regarded as preliminary. The composition of the feeding stuffs used is reported. When corn meal or skimmed milk was fed with hay, the coefficients of digestibility were calculated, taking into account the values found when timothy hay was fed alone. In connection with the digestion experiments, the heat of combustion of the feeding stuffs and feces was determined with a bomb calorimeter. Taking into account the fuel value of the food, feces, and urea, the available fuel value of the rations was calculated. A summary of the digestion experiments follows:

Coefficients of digestibility.

	Dry matter.	Organic matter.	Protein.	Fat.	Nitrogen-free extract.	Fiber.	Ash.	Available fuel value.
Silage from corn, sunflower heads, and horse beans:								
Sheep I.....	67.6	70.0	64.9	77.6	74.0	63.7	41.2	65.5

Sheep II.....	91.4	91.6	78.9	97.6	96.1	20.5
Sheep III.....	85.1	88.0	68.3	98.9	93.5	52.1
Average.....	98.6	90.7	76.9	98.1	95.3	49.5

In several of the experiments the coefficients of digestibility of protein are reported, allowance being made for the metabolic nitrogen in the feces. After treatment by pepsin and hydrochloric acid, the coefficients of digestibility of hay (mostly timothy) was 62.7 per cent; corn meal fed with hay, 86.8 per cent; skim milk fed with hay, 96.4 per cent; corn meal fed with hay and skim milk, 85.7 per cent. After treatment of the feces with alcohol, ether, water, and limewater, the coefficients of the feeding stuffs enumerated was found to be 62.2 per cent, 90.5 per cent, 97.5 per cent, and 93.5 per cent. A table is given summarizing all the coefficients of digestibility obtained with sheep at the Maine Station.

Spontaneous combustion of feeding stuffs, F. HOFFMANN (*Ztschr. Spiritusind.*, 1897, Nos. 35, 39, 41, 42, 45, 47, 49, 50; *abs. in Centbl. Agr. Chem.*, 27 (1898), No. 6, pp. 395, 396).—The author made a number of experiments with clover hay. His principal conclusions follow: Heat is generated in clover hay, oxygen being taken up from the air and the organic matter transformed into carbon dioxide and water. The water moistens the hay, and the moistened material ferments owing to the presence of bacteria. The fermentation also produces carbon dioxide and water as well as small amounts of hydrocarbons, hydrogen, organic acids, enzymes, etc. Heat is also produced by fermentation. The fermentation is more rapid if the clover is moistened at the beginning. However, the water produced by oxidation of the material is sufficient

to start it. The fermentation of the hay causes a temperature of 56° C. At this temperature a second and more violent oxidation takes place, and the temperature rises to about 90° . Other processes then take place which char the material and cause a slow rise of temperature to 130° . When this temperature is reached the hay rapidly heats and the charring takes place rapidly. All these processes destroy at least half of the material present. Theoretically, the temperature may rise to 190° .

According to the tests made, clover hay will become ignited at 150 – 200° . Therefore, the temperature may rise sufficiently high to cause spontaneous combustion. Oxygen from the air is essential to combustion. Spontaneous combustion is indicated by the hay becoming darker in color until it is finally black, by a sooty odor, and by smoke irritating to the eyes. The ash of the burned hay has a characteristic grayish-white appearance and feels like sand. The burned hay is surrounded by a layer of charred but not burned material, which is a poor conductor of heat.

Live stock, A. MACKAY (*Canada Expt. Farms Rpt. 1897, pp. 398–400*).—A brief statement is made concerning the cattle, swine, and poultry kept during the year at the experimental farms for the Northwest Territories, and a feeding test to compare wheat chaff, cut oat sheaves, and cut brome grass is reported. The test was made with 2 lots of 4 steers each and one lot made up of 3 steers and 1 cow. Lot 1 was fed wheat chaff, lot 2 cut oat sheaves, and lot 3 cut brome hay. In addition all the animals were given 2 lbs. of silage to each pound of dry fodder and 6 lbs. of ground barley and wheat (2:1) per head daily. The test covered 4 months. During the last 2 months the grain ration was increased to 8 lbs. per head daily. Lot 1 made a total gain of 1,025 lbs., lot 2 of 910 lbs., and lot 3 of 1,015 lbs. The profits are briefly discussed.

Experiments in feeding steers, S. A. BEDFORD (*Canada Expt. Farms Rpt. 1897, pp. 328–330*).—Statistics are given of the condition of the college herd and a test of the comparative value of hay and oat sheaves made with 2 lots of 4 steers each is briefly reported. Lot 1 was fed *ad libitum* a ration consisting of 18 lbs. of native hay (*Elymus virginicus*), 30 lbs. cut turnips, 5 lbs. chopped barley, and 2 lbs. of chopped oats. Lot 2 was fed *ad libitum* a ration consisting of 18 lbs. cut oat sheaves, with the same amount of turnips, barley, and oats. The test covered 93 days. The financial statement is based on native hay and oat sheaves at \$5 per ton, turnips at 5 cts. a bushel, chopped barley and oats at $\frac{1}{2}$ ct. per pound each. The steers in lot 1 made a daily average gain of 1 lb. 8 oz. and lot 2, 1 lb. 5 oz. The profit on lot 1 was \$55.42 and on lot 2, \$50.37.

“From the above it would appear that the cultivated native hay is worth rather more per ton than oat sheaves for fattening purposes.

“The yield of hay from this grass varies greatly from year to year, depending on

the rainfall, but it averages somewhat less than the yield of oat sheaves, under the same conditions.

"This grass succeeds remarkably well on dry uplands, where an oat crop would give small returns. Its roots are also very useful in preventing the drifting of soil."

Experiments on the feeding of steers, W. SAUNDERS (*Canada Expt. Farms Rpt. 1897, pp. 75-79*).—A test was made with 3 lots of 4 steers. During a preliminary period of 1 month all were given a ration consisting of 50 lbs. corn silage, 25 lbs. of roots, 5 lbs. of cut hay, and 5 lbs. of cut straw. The test proper began December 15, 1897, and covered 16 weeks, being divided into 3 periods of 8, 4, and 4 weeks respectively. Throughout the test all the steers were given the same coarse fodder ration as during the preliminary period. During the first period lot 1 was fed no grain in addition. During the second period the steers were given 2 lbs. of a mixture of equal parts of peas, barley, oats, and bran per head daily. During the third period this was increased to 6 lbs. The steers in lot 2 were given 2 lbs. of the same mixture per head daily during the first period, 4 lbs. during the second, and 6 lbs. during the third period. The steers in lot 3 were fed 4 lbs. of the same grain mixture per head daily during the first period and 6 lbs. per head daily during the second and third periods. The financial statement is based on corn silage and roots at \$2, hay at \$8, and straw at \$4 per ton. The grain mixture was valued at the rate of 1 cent per pound. The foods consumed and the gains made by the steers during each period are recorded in full. The animals weighed about 1,000 lbs. each at the beginning of the test. The average gain of the steers in lot 1 was 200.5 lbs.; lot 2, 194.5 lbs.; lot 3, 202.25 lbs.

"The results of the foregoing experiments appear to show that it is economical to withhold the feeding of grain, or to feed but little of it, during the first portion of the feeding period. The steers in lot 1 fed without grain for the first 8 weeks cost on an average 9.80 cts. per day for the whole period of 111 days; lot 2, 11.10 cts., and lot 3, 12.14 cts. per day. This shows an average cost of 1.30 cts. per day more for each animal in the second lot than for those in the first lot, and 2.34 cts. per day more for each steer in the third lot than for those in the first lot. This makes the average cost of feeding each animal in the second lot for the 111 days during which these tests were continued \$1.44 more than for those in the first lot, while the average gain in weight at the close of the experiment was 6 lbs. more per head in the first lot than it was in the second. The steers comprising the third lot cost on an average \$2.60 per animal more than those in the first lot, while the advantage in gain was only 1½ lbs. per head."

Experiments in fattening swine, W. SAUNDERS (*Canada Expt. Farms Rpt. 1897, pp. 80-86*).—Tests are briefly reported in which shorts; ground barley; ground Indian corn; shorts, a mixture of ground barley and Indian corn; a mixture of ground peas, barley, oats, and shorts with skim milk; unground oats; unground barley; unground peas; unground Indian corn; and a mixture of unground oats, barley, and peas were fed to swine. The grain was soaked in cold water before feeding, and the pigs were given all they would eat up clean. With the unground grain 3 lbs. of skim milk per head daily was fed. In

every case the foods consumed and the gains made are recorded. No comparisons are made and no deductions are drawn.

The amount of unground grain which passed through the swine undigested was determined by collecting the manure for one day and separating the undigested grain. When 14 lbs. of oats was fed, 2 lbs. 6 oz. of undigested grain was recovered. When dry, this weighed at the rate of 22½ lbs. per bushel. A germination test was made and 11 per cent of the grain sprouted. When about 17 lbs. of barley was consumed, 2 lbs. 2 oz. was separated undigested, weighing at the rate of 35 lbs. per bushel when dry. This was also tested as to its germinating power, but none of the kernels sprouted. When about 17 lbs. of peas was fed, 2 oz. was separated undigested. When tested none of the peas sprouted. From about 11 lbs. of corn consumed, 8 oz. of undigested grain was obtained, weighing at the rate of 40.25 lbs. per bushel when dry. Eight per cent of this grain sprouted when tested. When about 11 lbs. of a mixture of unground oats, barley, and peas was consumed, 10 oz. was recovered undigested. One hundred kernels of the mixed grain was tested as to its germinating power. Only 2 kernels of oats sprouted.

Poultry, S. A. BEDFORD (*Canada Expt. Farms Rpt. 1897, pp. 331-334*).—Brief statements are made concerning the poultry kept at the Manitoba Station, and a comparative experiment on the fattening of 10 turkeys and 10 chickens is reported. The chickens were made up of 6 White Plymouth Rock cockerels and 4 Black Minorca cockerels. Five turkeys and 5 chickens (3 Plymouth Rocks and 2 Black Minorcas) were fed in pens. The remaining turkeys and chickens were not confined. The turkeys and chickens in pens were given all they would eat up clean of a mixture of wheat, oats, and barley 2:1:1. In the morning the grain was fed chopped and wet with milk and in the evening it was fed whole.

“The turkeys were apparently more fond of oats than either barley or wheat, and towards the latter portion of the fattening period the proportion of this grain was increased with benefit.”

A little grain was given to the turkeys and chickens which were not confined in addition to the food which they could gather. The turkeys were fed from October 14 to November 25; the chickens from September 28 to November 26. The turkeys in pens weighed 32 lbs. 12 oz. at the beginning of the test and gained 20 lbs. 4 oz., consuming 6 lbs. grain per pound of gain. The turkeys running at large weighed 32.12 lbs. at the beginning of the test and gained 9 lbs. 4 oz. The food consumed and gains made are recorded for the 2 breeds of chickens. The chickens confined in pens weighed 20 lbs. 7 oz. at the beginning of the test and gained 11 lbs. and 2 oz., consuming a total of 57 lbs. of grain. The chickens running at large weighed 18 lbs. and 15 oz. at the beginning of the test and gained 4 lbs. 14 oz. The turkeys and chickens were killed and the shrinkage between the live and dead weights recorded.

"The penned fowl, both turkeys and chickens, when dressed, were much plumper and in every way more inviting than those which had been running at large, but the close confinement and heavy feeding appears to injure the chickens otherwise, the White Plymouth Rocks being badly 'off their feet,' while those running at large were quite healthy and active.

"Both turkeys and chickens made the largest increase during the first 3 weeks.

"After 6 weeks of close confinement chickens are probably kept at a loss.

"White Plymouth Rock chickens are better adapted for feeding in small pens than Black Minorcas.

"The White Plymouth Rocks were a better color and more attractive when dressed than the Black Minorcas.

"Penned turkeys shrunk 5 per cent less in dressing than those running at large.

"Chickens whether penned or running at large lost practically the same in dressing, viz, 34 per cent.

Adulteration of commercial and edible fats and oils, A. MÜNTZ, C. DURAND, and E. MILLAU (*Ann. Sci. Agron.*, 1898, II, No. 1, pp. 113-160; 2, pp. 161-186).

The effect of fresh gluten upon old flour, BALLAND (*Jour. Pharm. et Chim.*, 6. ser., 9 (1898), pp. 52-55; abs. in *Ztschr. Untersuch. Nahr. u. Genussmitl.*, 1899, No. 1, p. 156).—It is the gluten in old flour which causes it to spoil. By sifting the spoilt flour, the greater part of the material may be obtained which gives the flour its bad taste, smell, and high acidity. If fresh gluten is then added, and the flour sifted after about 14 days, a flour of improved smell, taste, and lower acidity is obtained. It is also more suitable for baking and makes better-flavored bread. These conclusions are based upon 8 experiments.

Diet in Italian hospitals, P. ALBERTONI (*Arch. Hyg.*, 34 (1899), No. 3, pp. 244-260).—Tables are given which show the foods supplied in a number of Italian hospitals, together with their composition.

An experiment in adding sugar to the ration of soldiers, LEITENSTORFER (*Deut. Mil. Aerzt. Ztschr.*, 27 (1898), No. 7, pp. 305-314).—Judging by the endurance manifested by the soldiers receiving it, the addition of sugar to the ration was beneficial.

Sugar in the ration of soldiers, J. DE PIETRA SANTA (*Jour. Hyg.*, 24 (1899), No. 1169, pp. 49-51).—Some of the recent experiments on the use of sugar are briefly reviewed, and the use of sugar in the French army is discussed.

The calculation of rations on the basis of heat or energy, J. KÖNIG (*Milch Ztg.*, 27 (1898), No. 47, pp. 742-744).—This is a brief summary of the methods of determining the heat of combustion and the application of such data to the compounding of rations for man and animals.

Nitrogenous feeding stuffs, C. S. PHELPS (*Connecticut Storrs Sta. Bul.* 18, pp. 16).—This is a condensation of an article entitled "Nitrogenous feeding stuffs and feeding formulas for dairy cows," by W. O. Atwater and C. S. Phelps (*Connecticut Storrs Sta. Rpt.* 1897, pp. 67-129; E. S. R., 10, p. 683).

Concerning sesame, A. HEBBRANT (*Landw. Vers. Stat.*, 51 (1898), No. 1, pp. 45-81, pl. 1).—The author describes the sesame plant, method of cultivation, gives the composition of the sesame seed, and discusses the manufacture of sesame cake and sesame oil. Considerable attention is devoted to a microscopical examination of sesame cake and the opinions of a number of investigators on the use of this cake are quoted. The article contains a bibliography.

Rape-seed cake, O. FÖRSTER (*Landw. Vers. Stat.*, 50 (1898), No. 5-6, pp. 371-447, fig. 1).—The manufacture of rape-seed cake and meal is discussed, the characteristics of rape-seed and similar cakes from a botanical standpoint pointed out, and many investigations on the composition, impurities, digestibility, and feeding value of rape-seed cake quoted. A method of estimating the fat in rape-seed cake is described and determinations reported, which are compared with determinations by other observers.

Rape-seed cake and its impurities, B. GRAM (*Landw. Vers. Stat.*, 50 (1898), No. 5-6, pp. 449-481, pls. 12).—The author describes the microscopical characteristics of rape-seed cake and its principal impurities.

What progress has been made in feeding meat meal? O. SCHELLENBERGER (*Fühling's Landw. Ztg.*, 47 (1898), No. 18, pp. 659-702; 19, pp. 717-721).—A general article summing up some of the experiences with meat meal.

The consumption of oxygen and the amount of oxygen required by mammals, J. ROSENTHAL (*Arch. Physiol.*, [Du Bois-Reymond], 22 (1898), pp. 271-281; *abs. in Zool. Centbl.*, 6 (1899), No. 3, p. 111).—Experiments with animals are reported in which a respiration apparatus which combined the principles of Regnault-Reiset and Voit-Pettenkofer was used.

The fate of carbon monoxid in the animal body, F. WACHHOLTZ (*Arch. Physiol.*, [Pflüger], 74 (1899), No. 3-4, pp. 174-186).

The relation of intestinal bacteria to nutrition, M. SCHOTTELIUS (*Arch. Hyg.*, 34 (1899), No. 3, pp. 210-243, figs. 3, *dgm.* 1).—Tests were made with chickens hatched under conditions which rendered them free from intestinal bacteria. After hatching they were supplied with sterilized food and water and the experimental conditions were such that the intestinal tract was kept free from bacteria. After a few days the chickens did not thrive and at the end of 17 days were very weak. The tests were not continued until the chickens died, but, in the author's opinion, they could not have lived more than 2 or 3 days longer. The chickens were killed and culture experiments were made, which showed that they were free from bacteria. Chickens raised under the same general conditions, but with no precautions to prevent their acquiring intestinal bacteria, grew normally. The author points out ways in which the experiments could be improved, but considers that they show the necessity of intestinal bacteria.

White cattle: An inquiry into their origin and history, R. H. WALLACE (*Trans. Nat. Hist. Soc. Glasgow, n. ser.*, 5 (1897-98), No. 2, pp. 220-233, figs. 32, pls. 4).—This is an extended study of the origin of the so-called white cattle of Great Britain.

Swine, A. S. BEDFORD (*Canada Expt. Farms Rpt. 1897*, p. 331).—Statistics are given of the pigs kept at the Manitoba Station farm.

Fattening swine, TANCRÉ (*Fühling's Landw. Ztg.*, 47 (1898), No. 20, pp. 770-774; 21, pp. 805-809).—A general discussion of the subject.

Report of the poultry manager, A. G. GILBERT (*Canada Expt. Farms Rpt. 1897*, pp. 231-245).—Among other points, somewhat detailed statements are given of the rations fed to the poultry during the year and their cost, the eggs laid and the prices received for the eggs, and the number of eggs set and chickens hatched. The importance of avoiding overfeeding is insisted upon. Unsuccessful attempts to cross a tame gander with a wild goose and a wild gander with a tame goose are recorded. The wild goose laid 6 eggs, but none of them hatched.

The new poultry plant, G. M. GOWELL (*Maine Sta. Rpt. 1897*, pp. 97-103, pl. 1).—A description of the new station poultry house, with a brief outline of experiments undertaken.

DAIRY FARMING—DAIRYING.

Studies in milk secretion, drawn from officially authenticated tests of Holstein-Friesian cows, H. H. WING and L. ANDERSON (*New York Cornell Sta. Bul.* 152, pp. 51-105).—The results are given of 210 separate seven-day tests of 153 registered Holstein cows, representing 8 different herds. The tests were made at different times, beginning in 1894, for members of the Holstein-Friesian Association of America, under the supervision of authorized representatives of the station. Some cows were tested twice and one was tested 6 times. The data given include the yield of milk and butter fat, fat content as determined by the Babcock test, and the food consumed. The results are grouped according to the age of the cows, 74 tests being of two-year-olds, 38 of three-year-olds, 35 of four-year-olds, and 63 of cows 5

years old or over. "According to the scheme [of equivalent records] adopted by the Holstein-Friesian Association for the admission of cattle into the Advanced Registry, each two-year-old must have produced 7.2 lbs. of fat, three-year-old 8.8, four-year-old 10.4, and each cow 5 years old or older 12 lbs. of butter fat in 7 days."

The data are discussed from various standpoints and the following general summary is given:

"The largest total yield of fat among two, three, four year old, or full-aged cows is, under every age, accompanied by the highest percentage of fat found among cows of that age.

"The smallest yield of fat for each age of animal is accompanied in only one case by the lowest percentage of fat, and that among the two-year-olds.

"The largest yields of milk do not contain the lowest percentages of fat, nor do the smallest yields of milk contain the highest percentages of fat.

"The stall-fed cows average higher in total yield of milk and fat and in percentage of fat than the cows at pasture.

"Equal quantities of the same kinds of food or similar quantities of different kinds of food produce widely varying amounts of milk and butter in different animals.

"To produce the same or similar amounts of milk and butter different animals require widely varying amounts of food.

"Cows, although of the same breed and raised in the same herd, vary greatly in their power to make an economic use of food.

"The cost of production is greatest among two-year-olds, and decreases gradually as the age increases up to 4 years, after which there is little if any variation.

"Within a period of 90 days from calving there is but little average variation in the percentage of fat among the different ages, except that the average of all the tests made at 31 to 60 days from calving is lower than for any other period.

"There is a slight variation in the average percentage of fat between two, three, and four year olds, and full-aged cows.

"The highest percentages of fat usually follow the shortest period between milkings. The lowest percentages of fat usually follow the longest period between milkings. Where the cows are milked at equal intervals the highest percentages occur most often at or near the noon hour, and the lowest percentages about equally often at morning and night, with a much larger number at midnight than at noon.

"The average range of variation during 7 days between the highest and lowest percentages of fat for individual animals is greater among four-year-olds and full-aged cows than among the younger animals.

"Neither the cows which show very great variation during 7 days in the percentages of fat nor those which show slight variation are abnormal animals, since their total product of milk and fat is near the average for their class.

"Cows which have been once tested and forced to their greatest capacity for a week rarely reach the same height of production again during the same period of lactation, even though the circumstances be otherwise most favorable, but frequently have made increased records in succeeding periods of lactation.

"There is an increase of only 7.5 per cent of milk and 7.7 per cent in fat of full-aged cows over four-year-olds, which shows that, on an average, cows have very nearly reached their largest production between the ages of 4 and 5.

"The 'equivalent record' plan is supported by the records of individual cows which have been tested at various times from 2 to 5 years of age, but not by the average records of all the cows of the different ages."

Butter investigations, H. KREIS (*Verhandl. Naturf. Forsch. Gesell. Basel, 12 (1898), No. 1, pp. 108-125*).—The author reviews, at considerable length, the principal literature on the volatile fatty acids of butter and the methods for their determination, and reports an investigation

conducted under his supervision. The plan of investigation included the examination of samples of butter from large dairies each week during the year by 6 Canton chemists, but in fact examinations were made much less frequently. The maximum and minimum results for all except the author's work were as follows: Specific gravity, 0.865-0.869; volatile fatty acids (Reichert-Meißl number), 26.6-33.7; saponification equivalent, 224-235.8, and index of refraction, 41-44.

The author made a systematic study, covering one year, of the butter produced by a herd near Basel, the maximum and minimum results of which are as follows:

Variation in butter from a herd during one year.

Month.	Volatile fatty acids.	Saponification number. ^a	Index of refraction.	Month.	Volatile fatty acids.	Index of refraction.
1896.			1897.			
November.....	27.0-31.5	223.2-233.2	42.8-45.5	May.....	21.9-22.7	44.5-46.0
December.....	27.5-29.2	222.7-224.5	44.0-45.5	June.....	18.5-21.6	44.5-46.0
1897.			1897.			
January.....	23.5-26.2	218.6-228.2	43.7-45.5	July.....	19.0-19.5	45.2-46.2
February.....	23.7-25.6	222.0-227.1	43.7-45.0	August.....	18.2-23.6	44.2-46.8
March.....	22.8-25.5	44.0-45.2	September.....	20.7-22.8	46.1-46.6
April.....	20.9-23.7	216.9-221.7	44.6-47.0	October.....	25.1-27.2	45.1-45.9
				November.....	22.6-26.3	43.9-46.1

^a As the index of refraction rose and fell with the volatile fatty acids, it was not determined after April.

The herd included fresh milk cows in varying number throughout the year. The low volatile fatty acids found in August were checked by a trial in which the author himself made butter from the milk drawn in his presence.

The author is inclined to believe that the time of year is not without effect on the composition of the butter. The results presented show the danger of condemning butter as adulterated on the basis of the volatile fatty acids. In the case of fresh butter the author recommends microscopic examination, and in the case of other butter he suggests that where possible a sample of milk from the dairy from which the butter emanated should be made into butter and examined.

Milk supplies of Pennsylvania, M. E. McDONNELL (*Pennsylvania Dept. Agr. Rpt. 1897, pp. 561-597*).—In addition to a general discussion of the characteristics of bacteria, the contamination of milk by disease germs, and the inspection and handling of milk, including protection from infection, pasteurization, use of preservatives, aeration, cooling, bottling, etc., the author presents a detailed report upon the examination of 352 samples of milk collected in 11 cities in the State. The data are tabulated and show the percentages of fat and total solids, specific gravity, acidity, total number of bacteria, and the number of liquefying bacteria per cubic centimeter, temperature on days of collection, and descriptive notes.

“The Pennsylvania supplies were studied at the hottest season of the year, and the number of organisms found is probably greater than it would be at any other time. The average number found in all of the milk examined, which included all

classes of milk, was over 5,500,000 per cubic centimeter. Ten samples contained 10,000,000 or more per cubic centimeter, and 10 others contained between 20,000,000 and 10,000,000 per cubic centimeter. These large numbers in a few samples make the total average very much higher than it should be. The worst samples were usually found at restaurants or with small retail dealers, so that such milk reaches fewer persons than that from the better supplies. Seventy-seven samples, 28 per cent of the samples tested, contained less than 100,000 bacteria per cubic centimeter. About 31 per cent contained less than 500,000 per cubic centimeter, and 121 samples, corresponding to about 45 per cent, contained less than 1,000,000 per cubic centimeter. . . .

"Of 312 samples tested for fat, 61 (18.7 per cent) were found to contain less than 3 per cent; 11 of these were below 2.75 per cent, 22 below 2.3 per cent, 12 below 2.25, and 7 below 2 per cent. Of 329 total solids determined 190 were below 12.9 per cent, 72 less than 11.5 per cent, and 37 less than 11 per cent. The specific gravity of 18 out of 329 samples was below 1.029. . . . The restaurant milk, as a class, was badly adulterated, the average per cent of total solids in all of the samples examined from this source (29) being only 11.33 per cent, and 13 of the samples were below 3 per cent fat and 11.5 per cent total solids. . . .

"Fifteen per cent of the samples examined were undoubtedly watered or skimmed."

Tuberculosis and milk supply, M. P. RAVENEL (*Pennsylvania Dept. Agr. Rpt. 1897, pp. 195-507*).—The author cites evidence bearing on the question of hereditary transmission of tuberculosis and on infection by means of tuberculous milk, and gives the data and conclusions of experiments in which guinea pigs were each subjected to an intraperitoneal injection of 10 cc. of milk from cows reacting to tuberculin and showing physical signs of tuberculosis. In summarizing 3 series of experiments, the author says that "15.4 per cent of the animals became tuberculous from the single dose of milk." In a later series of experiments animals were inoculated with sterilized and unsterilized milk but none in either lot developed tuberculosis.

"From these and other like experiments it is fair to conclude that the number of bacilli in the milk of tuberculous animals varies from day to day, although it is possible that in taking 10 cc. from the whole mass of milk, we may have missed bacilli which were few in number. Additional evidence has also been given to show that the bacillus of tuberculosis may pass into the milk of cows having general tuberculosis, but whose udders are perfectly healthy, so far as the most careful examination by competent veterinarians can show. . . . Milk from suspected cattle should be carefully sterilized before using, and especially should not be given to infants and invalids. The inspections of the animals should be at intervals frequent enough to keep the disease from gaining headway before being discovered."

Tubercle bacilli in butter, LYDIA RABINOWITSCH (*Deut. Med. Wchnschr., 25 (1899), No. 1, p. 5; abs. in Centbl. Bakt. u. Par., 1. Abt., 25 (1899), No. 2-3, p. 77; Science, n. ser., 9 (1898), No. 215, p. 232*).—The author, whose previous work on this subject was published in 1897, has recently conducted further experiments in Berlin, examining the product of 14 dairy stores. Of these, 13 showed no trace of true living tubercle bacilli, but in many instances pseudo tuberculous bacilli were found. The product from one store was found to contain tubercle bacilli; and during June and July the butter from this store was examined and 70 per cent of it found to contain living tubercle bacilli. Animals injected with the pseudo-tuberculous bacilli died of peritonitis.

The question whether they are harmful to human beings will be a matter for further investigation.

Pasteurization as applied to butter making, E. H. FARRINGTON and H. L. RUSSELL (*Wisconsin Sta. Bul.* 69, pp. 10, figs. 3).—The bulletin gives briefly the history of the use of pure cultures in butter making and describes a series of experiments, extending from February to August, which were made at the creamery of the Wisconsin Dairy School. Where pasteurization was practiced, the milk and not the cream was pasteurized. In 74 trials the milk was divided, a part being pasteurized, while the rest was used in the ordinary way. In addition to this the entire quantity of milk was pasteurized on certain days and on other days was used without pasteurizing. There were 110 cases of this kind. The unpasteurized milk was heated to about 85° for separating, while the pasteurized milk was heated to 155° F. in a Reid continuous pasteurizer. The cream was nearly always ripened with a starter made from the Boston butter culture, a pure culture of *Micrococcus butyri aromafaciens*. The other operations were similar to the ordinary methods of creamery butter making. The butter was scored twice by a butter expert in Chicago, the first time within 2 weeks after making. The second scoring for flavor was made several weeks later.

The culture starter was always found to be free from all foreign organisms, and it was demonstrated that practically sterile skim milk for the purpose of propagating the starter could be easily obtained in general creamery practice.

As to the efficiency of the sterilizer used, 13 samples of milk before heating showed an average of 32,000,000 bacteria per cubic centimeter, while the average of 16 samples after pasteurizing showed 1,800,000 bacteria, or a reduction of 94 per cent. As compared with an intermittent pasteurizer, the number of germs in the pasteurized milk is much larger.

The skim milk from the pasteurized milk kept from 12 to 24 hours longer than that from the unpasteurized milk, and in some cases was sweet after 48 hours.

The data for the butter making on 4 days in each month are tabulated, together with the scores of the butter made from pasteurized and unpasteurized milk, the scoring as affected by the size of the package, maximum, minimum and average composition of the butter from pasteurized and unpasteurized milk, efficiency of creaming milk heated to 85° and 155° F., and the churning record for the pasteurized and unpasteurized butter during the hot weather.

“A comparison of the flavor scores of 102 churnings of fresh unpasteurized butter with those of 75 of pasteurized butter shows the average score of each to be very nearly the same (40.69 unpasteurized, 40.63 pasteurized) on a basis of 45 as perfect flavor, but 5 per cent more of the unpasteurized than the pasteurized butter scored 42 points or better.

“The difference in the fresh scores is so slight that it is impossible from these scores to conclude that one system produces higher flavor than the other. The

scorer, however, claimed to be able to detect the pasteurized butter by its 'sweet,' 'curdy,' 'flat' taste, but did not materially reduce his score on this account. This conclusion is of material consequence, as it is usually claimed that as high a flavor cannot be secured in pasteurized butter as in that made in the ordinary way.

"Dividing the work into monthly periods (February to August), it can not be said that pasteurizing affects the quality of the butter more at one period than another.

"A comparison of the scores of 26 packages of butter, 8 lbs. and 60 lbs., from the same churning shows that the size of the package exerts an appreciable effect on the scorer's judgment of the butter flavor, the larger package scoring $\frac{1}{2}$ to 2 points higher than the smaller. On 'grain,' however, the size of package exerts no effect on the score. The importance of this deduction we believe to be considerable. Care should be taken, particularly in experimental work, to see that size of package is uniform throughout so as to eliminate this disturbing factor.

"The butter made from pasteurized milk was scored considerably lower on 'grain or body' than that made from unpasteurized milk. The pasteurizing process injures the 'grain and body' of the butter (according to American (Chicago) standards), as 62 per cent of the unpasteurized butter scored over 29 points on grain, while only 25 per cent of the pasteurized butter was given this score. This conclusion might be altered if butter had been sent to markets that are in the habit of using pasteurized goods.

"In our experiments both pasteurized and unpasteurized butter were quite uniform in quality, a slight difference existing in favor of the pasteurized goods.

"Pasteurizing the milk increased the keeping quality of the butter when stored for 2 to 4 weeks at butter cellar temperature, 50 to 60° F.

"Analyses of 11 samples of pasteurized and 19 of unpasteurized butter show but very little difference in the chemical composition. The average per cent of water in the pasteurized butter was 13.11 and in the unpasteurized 13.62.

"Heating the milk to 155° F. increases the skimming capacity of the separator, *i. e.*, more milk can be satisfactorily skimmed per hour at this temperature than at 85° F., provided the milk is heated by passing it over a hot surface. If heated to this high temperature by forcing steam into it, the skimming is unsatisfactory.

"More sediment accumulates in the separator bowl when the milk is skimmed at 155° F. than at 85° F. This is much more noticeable in ripe or tainted (sour) milk than in pure, sweet milk.

"A richer buttermilk was obtained from the pasteurized than from the unpasteurized churnings in hot weather, when the pasteurized cream, as a rule, was not so easily and thoroughly cooled as the unpasteurized. At other seasons when both churnings were made at about the same temperature there was not much difference in the amount of fat left in the 2 buttermilks.

"The yield of pasteurized butter in our experiments was on the average a little less than from unpasteurized butter. . . .

"The slight advantage as to keeping quality would in all probability be offset by the injury which it gives the grain as judged by American standards, and when we take into consideration the extra labor and expense involved in the process it is hardly to be expected that the system would yield increased returns over the ordinary method.

"In conclusion, we would say that according to the present demands of the American market, its introduction into creameries that already make a good product would hardly be justified."

The necessity for a butter standard, F. A. GENTH, jr. (*Pennsylvania Dept. Agr. Rpt. 1897, pp. 549-560*).—This consists essentially of descriptions and tabulated analyses of 100 samples of butter collected in Philadelphia and vicinity. The work was undertaken to furnish

data for determining a standard of percentages of fat, water, curd, and salt for butters in the State. The following table shows the average composition of the samples of each grade:

Average analysis of different grades of butter obtained in the Philadelphia market.

	No. of samples.	Water.	Butter fat.	Curd.	Salt, etc.
		<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
High-priced butter.....	20	11.56	85.29	1.10	2.05
Medium-priced dairy butter.....	33	9.54	86.69	1.36	2.41
Cheap dairy butter.....	2	11.31	84.37	2.22	2.10
Boiled or process butter.....	22	11.29	84.40	1.90	2.42
Miscellaneous butters.....	23	11.23	85.50	1.75	1.71

Of the 78 samples of unmelted butter examined only 1 contained less than 80 per cent of fat, and excluding 3 other samples on the ground of faulty manufacture—

“There remain only 3 samples of inferior quality which do not reach an 83 per cent butter-fat standard, to which any dairyman can easily bring his butter.

“The percentage of water, according to the results obtained, should not exceed 14 per cent at the very most, the standard adopted by Oregon.

“As to curd, over two-thirds contain less than 1.5 per cent, and less than 8 per cent of the total number of samples contain over 3 per cent. Of these, 2 are among those low in fats. Eight of the 11 samples, containing between 2 and 3 per cent, are under 2.5 per cent, leaving only 9 samples out of the whole lot over that figure, below which the curd in all butters should be reduced. The percentage of salt is about right when kept below 3 per cent.”

Boiled or process butter, T. J. EDGE (*Pennsylvania Dept. Agr. Rpt. 1897, pp. 175-178*).—Average analyses are given of different grades of butter obtained in the Philadelphia market including “boiled” or “new process” butter. These all show a content of butter fat above 80 per cent, which the author thinks is a fair standard for both the manufacturer and consumer. “Boiled” butter is described as being made from rancid and low-grade butter by a patent process in which the butter is reduced to its original oil, treated with alkali, freed from volatile oils, and churned with sour milk. From the standpoint of chemical analysis it can not be considered adulterated.

Feed and care of the dairy cow, H. M. COTTRELL, F. C. BURTIS, and D. H. OTIS (*Kansas Sta. Bul. 81, pp. 38, figs. 2*).—This consists of a popular discussion of various topics connected with the feeding and care of dairy cows, in which are given results of tests made to show the importance of clean milking and observations on the effect upon the fat content of milk of excitement of cows caused by shipping. The composition and value of various feeding stuffs are considered, and 100 rations are suggested.

In tests with 5 cows, the milk showed a gradual increase in the percentage of fat from the beginning to the end of the milking, with the exception of the last 2 pints drawn from each cow, which showed a sudden increase of 1 to 3 per cent. The average fat content for the 5 cows was 0.94 per cent for the first pint drawn and 6.84 per cent for the last.

The percentage of fat was determined in consecutive milkings for each of 5 cows immediately after their being shipped 100 miles on the cars. The data given show

irregular fluctuations in the fat content, continuing in one case to the ninth milking. The total yield of milk was much reduced.

Herd records, G. M. GOWELL (*Maine Sta. Rpt. 1897*, pp. 192-200).—This is a monthly record of 11 cows for 1897. The tabulated data include the yield of milk and butter, the kind and quantity of food, and a statement of cost of food per pound of milk and butter produced for each cow.

Effect of age of the cow on the yield and quality of milk (*Milch Ztg.*, 27 (1898), No. 53, p. 841).—The milking trials made in Algan since 1894 are said to indicate in general that the yield of milk and fat increases up to and including the fifth calving, after which it gradually decreases, although there are exceptions in the case of individual cows. The milk is richest in fat after the third and fourth calvings.

The dairy markets of Pennsylvania, H. HAYWARD (*Pennsylvania Dept. Agr. Rpt. 1897*, pp. 598-617).—This treats in a popular manner of the production and marketing of milk, butter, and cheese in Pennsylvania. The author discusses boards of trade in their relation to dairying, and quotes the constitution and by-laws of the Elgin board of trade.

Dairying (*Pennsylvania Dept. Agr. Rpt. 1897*, pp. 247-282).—This contains 11 papers read at farmers' institutes in Pennsylvania during 1896-97, treating in a popular manner of various subjects connected with dairying.

Milk testing on a large scale by the Nahm method (*Milch Ztg.*, 28 (1889), No. 1, pp. 5, 6, figs. 3).—Slight modifications of the apparatus used in this method (E. S. R., 6, p. 474), with an arrangement for making a number of tests at the same time.

Dairy and milk inspection, C. A. CAREY (*Alabama College Sta. Bul. 95*, pp. 211-258).—This is a popular bulletin treating of the testing of dairy herds for tuberculosis, the feeding and care of cows, the composition and analysis of milk, milk adulteration, bacteria and yeasts in milk, including pathogenic germs, pasteurization, disinfection of barns and dairy houses, the milk ordinance of Montgomery, Alabama, and a bibliography of works consulted in the preparation of the bulletin.

Testing dairy products by the Babcock test, J. M. BARTLETT (*Maine Sta. Rpt. 1897*, pp. 61-96, figs. 8).—This is largely a compilation treating of the subject in a popular manner. The apparatus required is figured and described, and detailed directions are given for sampling and testing milk, skim milk, buttermilk, whey, cream, butter, cheese, and condensed milk, special attention being given to sampling, weighing, and testing cream. A balance specially designed for weighing cream samples is described. The use of the lactometer and fat test in the detection of adulterated milk is discussed.

Tilsiter cheese and its manufacture, R. EICHOFF (*Milch Ztg.*, 28 (1899), No. 4, pp. 52, 53).—Describes the method employed in factories in West Prussia.

Cheese poison, R. C. KEDZIE (*Amer. Cheesemaker*, 13 (1899), No. 156, pp. 2, 3).—A popular explanation of the changes in milk and dairy products in general.

VETERINARY SCIENCE AND PRACTICE.

Report of the State veterinarian, L. PEARSON (*Pennsylvania Dept. Agr. Bul. 31*, pp. 119-150).—The report includes detailed statements of the work of the department during the year.

*The number of cattle tested up to June 1, 1897, was 9,108; the number of these that were found to be tuberculous and condemned was 1,839. The percentage of tuberculosis, therefore, was 20.39. Since June 1, 4,887 cattle have been tested with tuberculin, and of these 671 were found to be tuberculous and killed, equivalent to 13.73 per cent. Considering the manner in which the herds to be tested are selected and the wide distribution of the work, covering practically all parts of the State, it would seem fair to assume from this showing that many of the most thoroughly infested herds have been discovered and disposed of, and that the percentage of

tuberculosis among cattle at large is being steadily and rapidly reduced. This is indeed an encouraging condition, and I believe that it justifies the plan that has been adopted for meeting this disease."

The author discusses symptoms, methods of treatment, and prevention of rabies, glanders, hog cholera, abnormal (depraved) appetite of cattle, blackleg, tuberculosis, infectious abortion of cattle, catarrhal or broncho-pneumonia of cattle, and anthrax. Some of the more important deductions follow.

Reports from different parts of the State indicate that rabies is more prevalent than was suspected. The fact that infected dogs may spread the disease is recognized and preventive measures are suggested.

The author believes that by continued vigilance in destroying glandered horses and disinfecting the places occupied by them the disease may be stamped out. The value of mallein in diagnosing difficult cases of glanders is pointed out.

Vaccination for blackleg has been practiced on a few infected farms in Pennsylvania during the past year with very encouraging results. No injury has resulted from the treatment, and thus far no cases have developed among the animals protected."

Attention is drawn to the fact that no injuries have been reported due to the use of tuberculin as a test for tuberculosis. The author notes that many investigations on methods of dealing with this disease are needed, and that the Department has experiments in progress which it is hoped will throw light on some of the obscure features of the tuberculosis question.

The importance of the satisfactory disposal of carcasses of animals affected with anthrax is insisted upon. Burning is recommended, and when this is not possible the carcass should be covered with lime and deeply buried in some locality where there is no danger of contaminating streams. The premises where the animal died should be thoroughly disinfected.

"Whenever anthrax appears it is important to so dispose of the carcasses of its victims that the soil may not become contaminated with its germs. This is best accomplished by burning the carcasses without opening them, because wherever a drop of blood falls the seeds of the disease may become established. If possible, the carcass should be burned on the spot where the animal dies. If this can not be done, on account of the surroundings, the carcass should be loaded onto a stone boat and dragged to a suitable place, and there thrown upon a loose pile of wood and cremated. If burning is not possible, the next best method of disposing of these carcasses is to bury them deeply away from water courses (where they would drain into a stream and might be washed out) and covered well with lime before the earth is thrown over them. Such graves should be so deep that there will be no danger of future accidental disinterment. If the animal dies in the stable, the premises occupied by it should be cleaned in the most thorough manner and disinfected by a thorough washing and saturation with a solution of bichlorid of mercury (corrosive sublimate) 1 part to 1,000 parts of water. As this solution is poisonous it must be used with care. The germs of anthrax prefer low moist soils and remain alive longest in such places. The infection of the soil of a given region with the germs of anthrax is a serious matter, and endangers the live stock for a considerable period thereafter."

Outbreaks of anthrax among the employees in tanneries in Pennsylvania and among cattle in the neighborhoods are described in considerable detail.

"These two outbreaks illustrate one of the important ways in which anthrax is carried long distances. Unfortunately, there appears to be no simple way by which we can protect ourselves from the danger resulting from the use of such infected hides. No method has yet been discovered for the safe, efficient, and economical disinfection of hides, and although attempts have been made upon the part of the Federal Government to plan and enforce such disinfections in the case of hides from suspected sources, they appear to have been evaded in a few cases. It seems that in some partly civilized countries the hides are removed from animals that die of anthrax and are exported. There is a provision against the importation of hides from districts where anthrax is known to exist, but as the hides do not always come directly from such districts the regulation does not fully prevent their importation. It has been shown by Griglio, an Italian investigator, that the spores of the anthrax bacillus are even more resistant than is usually supposed, and that the usual, so-called, disinfection to which wool and hair and hides are sometimes submitted is futile. He has found that the salting of hides and steeping of the skins in brine does not destroy the spore, nor does soaking of the dried hides in milk of lime, nor prolonged drying; and other observers have noticed that treatment even with arsenic does not disinfect the skins. One reason for this may lie in the fact that spores exist not only on the surface of the skin, but in the deeper parts, whither they are carried in the circulation.

"With continued careful oversight of the localities in which anthrax has developed, the proper disposition of all suspected carcasses and a judicious use of vaccine, there is every reason to believe that the disease can not only be kept within present bounds but that it will in time be suppressed."

The other diseases enumerated are treated of in less detail.

Effects of tuberculin on tuberculous cows, F. L. RUSSELL (Maine—*Sta. Rpt. 1897, pp. 159-166, pl. 1.*)—In a previous publication (*E. S. R., 9, p. 891*) a partial report was made of the progress of tuberculosis in a herd of 10 cows, which had given reaction to the tuberculin test. During the year the investigation was continued. The cows were quarantined in a light and well-ventilated stable and well fed and cared for. In summer they had the run of a small pasture, and in winter were allowed the run of a sunny yard when the weather permitted. The attempt was made to keep the animals in as healthy condition as possible without resorting to any unusual means. From time to time the cows were tested with tuberculin and were finally destroyed, *post-mortem* examinations being made.

In the author's opinion the investigation shows that—

"Kept under exceptionally good conditions as these cattle were, 5 of them kept the disease in check, so that it made practically no advancement. In the case of 3 others but little advance was made, while in 2 cases the disease had nearly reached a fatal termination when the animals were killed. On the whole, we can not see that the exceptionally good care that these animals received had any effect on the progress of the disease. It may have retarded the progress of the disease, but if so, the fact is not sufficiently clear to lend much weight to the argument that tuberculosis can be successfully controlled by simply maintaining animals under good hygienic conditions. Twenty per cent of deaths is probably as high a percentage as one could reasonably expect among ordinary tuberculosis herds kept under poor or only fair hygienic conditions if, to begin with, all cases that presented any physical symptoms of disease were removed."

Four pigs and 15 calves were fed milk from the tuberculous cows; the pigs being given some meal and the calves a little hay in addition. The pigs were killed when they weighed about 175 pounds, and the calves when from 6 to 8 weeks old. One of the pigs and 2 of the calves were found to be tuberculous.

Parturient apoplexy and its modern methods of treatment, POEPEL (*Milch Ztg.*, 27 (1898) No. 40, pp. 628, 629).—In this article, which is a reprint from another journal, the author summarizes the opinions regarding causes and treatment of parturient apoplexy (*Eclampsia puerperalis*) in milch cows and reports results of recent investigations. According to a Danish veterinarian, Schmidt von Kolding, the disease is caused by decomposition of the secreting cells in the udder when the milk secretion begins after calving, a leukomaine being formed from the cholesterol bodies, this leukomaine being the direct cause of the disease. The method of treatment proposed is injection into the udder of a solution of 10 gm. of potassium iodid in a liter of freshly boiled water. The solution should be inserted at a temperature of 40 to 42° C. A milk catheter with a wide canal attached to a funnel by means of a rubber tube may be used. Instruments should be disinfected. If complications due to the effect of potassium iodid on the heart are feared, sodium iodid may be used in its place. It is stated that 92 per cent of the cows treated by this method recovered. The percentage of recovery by the usual methods of treatment was 50 to 60.

Life history of the sheep-scab mite (*Psoroptes communis*), C. P. GILLETTE (*Canad. Ent.*, 31 (1899), No. 1, p. 9).—In order to ascertain how long a time should intervene between the first and second dippings of sheep for the cure of scab, the author undertook to determine the period of incubation and also the time elapsing from the deposition of the egg to the time that the mite from that egg, if a female, may itself deposit eggs. It was ascertained that it requires 4 days for a newly deposited egg to hatch and the entire time elapsing from egg to egg would be about 14 or 15 days. As there would be eggs in all stages of incubation upon a sheep when the latter is dipped for the cure of scab, the author states that a second dipping should follow not sooner than 5 nor later than 10 days after the first dipping.

Tuberculosis of cattle, B. BANG (*Pennsylvania Dept. Agr. Rpt. 1897*, pp. 480-494).—A general article. The topics covered are the desirability of freeing herds from tuberculosis; infection of cattle stabled and herded together; value of sanitary conditions; infection of swine, calves, and other animals, and man by the use of milk of tuberculous cows; accuracy of the tuberculin test; success of measures against tuberculosis in Denmark; and the advantages of suppressing bovine tuberculosis.

Tuberculosis, W. SAUNDERS (*Canada Expt. Farms Rpt. 1897*, pp. 70-75).—A detailed report is given of the results of a tuberculin test at the central farm.

Brief notes are also given of testing the herds at the experimental farms at Brandon, Indian Head, and Agassiz.

Remarks on tuberculosis in cattle, W. LONG (*Lancet* [London], 1898, No. 15, p. 932).

A comparison of the temperatures of healthy and tuberculous cows, F. L. RUSSELL (*Maine Sta. Rpt.*, 1897, pp. 167-172).—The temperature of 6 tuberculous and 6 healthy cows was taken 3 times a day for 40 days. The results are summarized in tabular form. In the author's opinion the results are negative so far as showing any difference in temperature between healthy animals and those slightly tuberculous.

The prophylaxis of tuberculosis, E. LECLAINCHE (*Rev. Tuberculose*, 1898, No. 3, pp. 257-268).

A case of tuberculosis in a horse, G. PORTET (*Rev. Vet.*, 24 (1899), No. 2, pp. 73-87).—A report of a case of tuberculosis and a *post-mortem* examination.

Tuberculous meat and milk, J. NIVEN (*Med. Mag. London*, 1898, No. 10, pp. 786-793).

Contributions to study of the so-called foot rot in cattle, IMMINGER (*Wchenschr. Tierheilk.*, 1898, No. 41, pp. 377-382; 42, pp. 389-393).

On the influence of lecithin and lecithin products on the biology of the splenic fever bacteria, W. TARANUCHIN (*Russ. Arch. Pat. Klin. i Med. Bact.*, 6 (1898), No. 1).

Concerning *Streptococcus equi*, E. CAPPELLETTI and M. VIVALDI (*Arch. Hyg.*, 34 (1899), No. 1, pp. 1-21).—The authors cultivated *Streptococcus equi* on artificial media and report inoculation experiments with mice, rabbits, and guinea pigs.

Infectious cerebro-spinal diseases of horses, SPERLING (*Deut. Tierärztl. Wchenschr.*, 1898, No. 41, pp. 358, 359).

Anchylolysis of horses, ST. VON RATZ (*Monatsh. Prakt. Tierh.*, 10 (1898), No. 2, pp. 49-61).

An essay on the diseases of lower animals transmissible to man, E. MARRISON (*Vet. Jour.*, 1898, No. 10, pp. 241-252).

A contribution to the subject of the specific effect of serums producing immunity, C. MANN (*Arch. Hyg.*, 34 (1899), No. 3, pp. 179-191).—A number of experiments on the effect of different serums upon bacteria were made with rabbits.

Bacteriological investigations of animal lymph, W. DREYER (*Ztschr. Hyg. u. Infektionskrankh.*, 27 (1898), p. 116; *abs. in Hyg. Rundschau*, 9 (1899), No. 4, pp. 188-191).

Toxic effects of boracic acid, J. J. EVANS (*British Med. Jour.*, 1899, No. 1987, p. 369).—The author reports the observation of toxic effects when considerable amounts of boracic acid were taken for some time.

Concerning ricinus poison, A. CUSHNY (*Arch. Exper. Path. u. Pharmakol.*, 41 (1898), pp. 439-448).—A chemical study of ricinus poison is reported.

Abortion, miscarriage, sinking, slipping the calf, L. PEARSON (*Pennsylvania Dept. Agr. Rpt.*, 1897, pp. 478-480).—A general article. The removal of cows that are affected with this disease is insisted upon, as well as thorough disinfection of surroundings, destruction of fetus, etc., disinfection of genital passages, and similar preventive measures.

List of cases treated by the station veterinarian during 1894 (*Alabama Canebrake Sta. Bul.*, 18, pp. 15, 16).

Veterinary medicines: Their nature, properties, and doses, T. J. EDGE (*Pennsylvania Dept. Agr. Bul.*, 35, pp. 23).—The author defines many of the terms applied to veterinary medicines, discusses the actions of medicines, and gives briefly the nature, properties, effects, and doses of the more important remedies.

Anatomical preparations of the horse, R. SCHMÄLTZ (*Präparirungen am Pferd*, Berlin: R. Schoetz, 1898, pp. VIII + 240).—According to the subtitle this volume contains directions for the preparation of all the specimens necessary for studying the anatomy of the horse.

TECHNOLOGY.

Further experiments in the preservation of grape juice, J. CRAIG (*Canada Expt. Farms Rpt.*, 1897, pp. 103-105).—In continuation of previous work (E. S. R., 9, p. 895) the following experiments were made on the juice of 5 varieties of grapes—Clinton, Black Elvira,

Bacchus, Brant, and Concord: Juice heated to 170° for 10 minutes, to 160° for 10 minutes, 150° for 10 minutes, 130° for 10 minutes on 2 consecutive days, not heated, and bottled cold but treated with formalin, $\frac{1}{2}$ to 1 per cent. Sugar was used in all cases at the rate of 2 oz. to each pint of juice. The results are summarized as follows:

"(1) Formalin while a proved ferment arrester imparts such a disagreeable flavor to the juice that it can not be used, at least as strong as in the proportion of $\frac{1}{4}$ per cent.

"(2) Sugar added to the juice with formalin masked the flavor of the latter somewhat, but did not obliterate it entirely.

"(3) Salicylic acid, 0.175 gm. with 2 oz. sugar to each pint produced the most palatable beverage.

"(4) Samples were successfully preserved when heated for 10 minutes at 160° with sugar at the rate of 2 oz. to each pint of juice. Duplicate samples without sugar were also successfully preserved but were not generally as palatable as the former.

"(5) 160° F. seems to be the lowest safe temperature that may be used in the preservation of grape juice. The juice may be held at this temperature for 15 or 20 minutes without imparting to it any unpleasant boiled flavor."

Utilization of Indian cornstalks in Russia, W. R. HOLLOWAY (*U. S. Consular Rpts.*, 1898, No. 217, pp. 216, 217).—A brief account is given of a trial by the Russian Admiralty of cellulose packing made from the pith of cornstalks.

The cornstalk as a commercial commodity (*Drainage Jour.*, 20 (1898), No. 11, p. 313).—The use of the outer hard portion of the cornstalks ("shives") for paper making is briefly discussed.

The nonsugars in beets in their relation to sugar manufacture, A. RÜMPLER (*Die Nichtzuckerstoffe der Rüben in ihren Beziehungen zur Zuckerfabrikation*. Brunswick: Friedrich Vieweg & Sohn, 1898, pp. 523).

Progress in the manufacture of beet sugar in 1898, E. O. VON LIPP MANN (*Chem. Ztg.*, 23 (1899), No. 11, pp. 106-109).—A résumé of work on the growing of beets, and the science and technology of the manufacture of sugar, disposal of by-products, etc.

The manufacture of starch from maize in Russia, L. KRAMM (*Abh. in Bnd. Assoc. Chim. Sucr. et Distill.*, 16 (1898), No. 4, p. 372).

AGRICULTURAL ENGINEERING.

Fourth biennial report of the State engineer of Wyoming, 1897-98 (*Cheyenne*, 1898, pp. 304, pls. 11, figs. 11, map 1).—Among the subjects discussed are adjudication of water rights, measurements of streams, agricultural problems and possibilities of northern Wyoming, reservoirs, and selecting State lands (especially for grazing purposes).

First biennial report of the State engineer of Utah, 1897-98 (*Salt Lake City*, 1899, pp. 86, figs. 18).—This includes a summary account of the work of the office of irrigation engineer during 1897-98, a discussion of irrigation legislation in the State, and instructions as to the preparation of plans for dams or dikes and the measurement of water (including tables of discharge over rectangular weirs).

Fourteenth annual report of the hydraulic engineer on water supply, Queensland, 1897-98 (*Brisbane*, 1898, pp. 59, pls. 4, dqms. 13, maps 5).—This report summarizes the operation of the water supply department of Queensland during the year ending June 30, 1898, giving an account of surveys in connection with flood warnings and data relating to artesian wells and irrigation. The report is profusely illustrated with plates, maps, and diagrams.

On the preservation of the water supply, being the principal results of four years' work of the expedition for the investigation of the sources of the main

rivers of European Russia (*St. Petersburg, 1898, pp. 53; rev. in Selsk. Khoz. i Lyesov., 190 (1898), No. 8, pp. 456, 457*).—During the 4 years of its existence the expedition has studied systematically 8 drainage basins with a total area of more than 4,000,000 acres. As a result of these investigations a series (16 volumes) of publications by the expedition has appeared under the title of "Works on the hydrogeological, hydrotechnical, forest, geological, soil, and meteorological phases of the general water question in the central watershed of Russia." The present publication is a summary of these works.—P. FIREMAN.

Report on the prospects of irrigation and water conservation in New South Wales, F. J. HOME (*Sydney: William Applegate Gullick, 1897, pp. 29, diagrams, 36, maps 4*).—Discusses both surface and artesian supplies, but devoted especially to the feasibility of constructing 2 canals, one on the Murrumbidgee River, the other on the Murray River. Maps are given of the proposed work, and diagrams show the discharge of the 2 rivers named at different seasons of the year.

Field trials of plows, F. BOKELMAN (*Tidsskr. Landökon., 17 (1898), No. 5-6, pp. 354-378*).—An account of a 4-day field trial in Denmark with plows of different makes—4 American swing plows, 1 German plow, and 17 of the common Danish plows.—F. W. WOLL.

STATISTICS—MISCELLANEOUS.

Thirteenth Annual Report of Maine Station, 1897 (*Maine Sta. Rpt., 1897, pp. 211*).—This contains reports of the director for the year ending December 31, 1897, and the treasurer for the fiscal year ending June 30, 1897; acknowledgements; various articles noted elsewhere; reprints or abstracts of Bulletins 32-40 of the station on the following subjects: Three troublesome weeds (*E. S. R., 9, p. 113*), fertilizer inspection, 1897 (*E. S. R., 9, p. 436*), box experiments with phosphoric acid from different sources (*E. S. R., 9, p. 436*), the currant fly, gooseberry fruit fly (*E. S. R., 9, p. 673*), testing seeds (*E. S. R., 9, p. 653*), feeding-stuff inspection (*E. S. R., 9, p. 682*), fertilizer inspection, 1897 (*E. S. R., 9, p. 739*), stock-feeding suggestions (*E. S. R., 9, p. 983*), and celery (*E. S. R., 9, p. 950*); and a reprint with minor additions of Bulletin 12 of the station on ornamenting home grounds (*E. S. R., 10, p. 355*).

Preliminary report of the municipal agricultural experiment station at Vyatka for 1897 (*Vyatka, pp. 61; rev. in Selsk. Khoz. i Lyesov., 190 (1898), No. 9, pp. 716, 717*).

Agriculture in the Hawaiian Islands, H. W. WILEY (*Jour. Franklin Inst., 147 (1899), No. 1, pp. 31-52*).

Statistics of the glucose industry (*Chicago: Glucose Sugar Refining Co., 1898, pp. 63*).

Development of the text-book of agriculture in North America, L. H. BAILEY (*Book Reviews, 7 (1899) No. 2, pp. 43-46*).—This article discusses the development of the text-book on agriculture, and reviews briefly the most important works published since 1837 in their chronological order.

NOTES.

ARKANSAS UNIVERSITY AND STATION.—G. L. Teller has resigned his position to take charge of the chemical work in Chidlow Institute of Milling and Baking Technology, recently established in Chicago by David Chidlow, who was formerly chemist to the Pillsbury-Washburn Flour Mills Company, of Minneapolis.

IDAHO UNIVERSITY AND STATION.—The State legislature has made an appropriation of \$14,000 to finish the university building and \$20,000 for maintenance. This is the largest appropriation ever made by the State for the support of the university. A very successful series of farmers' institutes have been held in the State this winter under the direction of H. T. French, agriculturist of the station. This work is of very great value, inasmuch as the conditions affecting agricultural operations vary so much in different parts of the State. It is the first organization of farmers' institutes in the State. The agriculturist will make a special study of forage plants this season.

ILLINOIS UNIVERSITY AND STATION.—The term of office of the following members of the board of trustees of the university has expired: J. Irving Pearce, Samuel M. Inglis, Napoleon B. Morrison, James E. Armstrong, and Isaac S. Raymond. In their stead have been elected the following: W. H. Fulkerson, of Jerseyville, *ex officio* trustee, as president of the State Board of Agriculture; Alfred Bayliss, of Springfield, *ex officio* trustee, as State Superintendent of Public Instruction; Mrs. Alice A. Abbott, of Chicago; Frederick L. Hatch, of Spring Grove; and Augustus F. Nightingale, of Chicago. The board of trustees has appointed the following as members of the advisory board of the station: W. H. Fulkerson and F. L. Hatch (trustees) and Henry Augustine, of Normal, *vice* E. A. Riehl.

INDIANA STATION.—W. B. Anderson has resigned his position as assistant agriculturist of the station and retired to his farm at Otwell, Indiana, which he is to manage in the future. The vacancy has been filled by the appointment of J. H. Skinner, B. Sc., a graduate of the School of Agriculture of Purdue University.

KANSAS COLLEGE AND STATION.—W. H. Phipps, recently a member of the board of regents, has become secretary of the college and station. The following new members of the board of regents have been appointed for the term ending April 1, 1903: William Hunter, of Blue Rapids; J. M. Satterthwaite, of Douglass, and E. T. Fairchild, of Ellsworth. In addition to the appropriations previously noted (E. S. R., 10, p. 799) the State legislature has appropriated \$16,500 for additional buildings and equipment for the mechanical department, \$4,000 for the enlargement of the library, and \$2,000 for farmers' institutes. The station has issued a press bulletin on soy beans, which has attracted considerable attention.

OHIO STATION.—On April 11 the station killed 12 cattle which had been under experiment with the tuberculin test for periods varying from a few months to nearly two years. Several hundred people were present, many coming from distant parts of the State. Perhaps the most conspicuous outcome of the experiment was the demonstration that when the tuberculin test is applied in season, affected cattle may be fattened and disposed of for beef long before the disease has become so generalized as to render their meat unsafe for food. Repeated injections of tuberculin seemed to have had a retarding rather than an accelerating effect upon the progress of the disease.

SOUTH CAROLINA COLLEGE AND STATION.—The board of trustees at their last regular meeting took the initiatory steps looking to a permanent and complete

separation of the experiment station work from that of the farm and college. At a recent meeting the chairs of botany and entomology were consolidated. This consolidates the work of these two sciences in the station also. As previously noted, live stock and dairying have been consolidated and placed in charge of C. M. Conner. Important work has been recently done by the botanist and entomologist in investigations of fungus diseases of rice. Preparations are being made to experiment on a more elaborate scale with grasses and legumes. Experiments have also been inaugurated with hop culture. A short bulletin entitled "Suggestions to auxiliary clubs" has been issued to induce cooperation of farmers' clubs with the station. Farmers' institutes will be held, where desired, during the summer and made more strictly agricultural than hitherto.

WYOMING UNIVERSITY AND STATION.—The State legislature has provided a $\frac{3}{8}$ mill tax for four years, the proceeds of which are to be used in the construction of a new building at the university. It is probable that a science hall will be built, costing about \$22,000, and that work on it will be begun the coming season. This will undoubtedly greatly benefit the station by giving increased facilities for scientific work. The following new members have been appointed on the board of trustees: S. Conant Parks, of Lander, and J. A. Riner, of Cheyenne, *vice* James A. McAvoy and J. O. Churchill, whose terms of office have expired.

PERSONAL MENTION.—Arthur Devarda, adjunct to the agricultural-chemical experiment station at Vienna, has been transferred to a similar position in the station at Görz. He will be succeeded by Adolf Halla, former assistant.

Prof. Dr. R. von Wettstein, who succeeds the late Dr. A. von Kerner as professor of botany and director of the gardens and museum of the University of Vienna, assumed his new duties April 1.

Prof. Emerich Meissl, director of the agricultural-chemical experiment station at Vienna, has been appointed counselor ("Ministerialrat") to the German agricultural ministry. Dr. F. W. Dafert, director of the agricultural institute at Campinas, Brazil, has been appointed director of the station in his stead, and the place of the latter has been filled by Dr. Gustav Dutra.

The agricultural experiment station at Cöthen, Germany, which was founded in 1864, has been discontinued, owing to the death of the director, Dr. F. Heidepriem.

Dr. Wilhelm Schimper, formerly associate professor of botany at the University of Bonn, has been appointed to a chair in the University of Basel.

The British Government has established a botanic garden and experiment station in Uganda, Northeast Africa, under the direction of Alex. White.

J. H. Holland has been appointed director of the botanic gardens in Old Calabar, Western Africa.

MISCELLANEOUS.—According to *The Gardeners' Chronicle*, it has been decided to hold an arboricultural and pomological conference in connection with the horticultural section of the Paris Exposition. Preliminary papers will be accepted dealing with the following subjects: Fruit farms, cultural and economic principles, choice of suitable varieties and their use, fruit planting by roadsides, harvesting and preservation of fruit, packing fruit, cider trees and fruits—their cultivation and uses, atmospheric agencies—their influence on forced fruit trees and vines, vegetable physiology as regards fructification, practice of grafting and pruning, tariffs and conditions of transport for trees and fruits, insects, diseases, remedies, manures and fertilizers, the propagation of varieties of fruit for colonial cultivation, tuition in fruit culture, garden schools, public instruction, congresses, etc. The details of the organization will be under the direction of a committee, of which Charles Baltet will be chairman.

A semimonthly journal, *La Industria Azucarera*, devoted to the cane-sugar industry in all of its branches, and intended for circulation in all the Spanish-American countries which produce sugar, has recently been started by the Sugar Industry Company, 123 Liberty street, New York City.

SUBJECT LIST OF ABSTRACTS.

CHEMISTRY.

The albuminoid of wheat gluten, K. Morishima.....	917
The inversion of sugar by salts, L. Kahlenberg, D. J. Davis, and R. E. Fowler..	918
The rapid detection of perchlorate in nitrate of soda, P. Nyssens.....	918
On the volatile and insoluble fatty acids in butter, R. Henriques.....	919
Chemical division of the Rhode Island Station, H. J. Wheeler	919

BOTANY.

Systematic plant introduction, D. G. Fairchild	927
Grass culture in Iceland, P. Teilberg	920
Gram, chick-pea, or Idaho pea, J. G. Smith.....	928
Thirty poisonous plants of the United States, V. K. Chesnut	928
The seeds and seedlings of some Amentiferae, W. W. Rowlee and G. T. Hastings..	921
Temperature of plants, F. Schleichert.....	921
Movement of plant food before the fall of the leaf, F. Ramann.....	922
Starch distribution as affected by fungi, B. D. Halsted.....	923
Poisonous properties of wild-cherry leaves, F. W. Morse and C. D. Howard ..	923
Concerning proteid synthesis in green plants, B. Hansteen	925

	Page.
Formation of albuminoid substances in plants by the reduction of nitrates, A. Hébert.....	925
The influence of Nitragin on the growth of various legumes, M. Maereker and H. Steffeck	926
Experiments with Nitragin, A. P. Aitken.....	926
On the use of almit in the cultivation of cereals, L. Malpeaux.....	927
Production of new types of forage plants—clovers and grasses, A. N. McAlpine.....	927
Methods in planktology, G. W. Field.....	929
The Point Judith pond, G. W. Field.....	929
METEOROLOGY—CLIMATOLOGY.	
Meteorological report, N. Helme.....	930
WATER—SOILS.	
Lysimeter experiments, J. Hanamann.....	930
Composition of drainage water from fertilized and unfertilized moor soils, with special reference to nitrogen, B. Tacke, H. Immendorff, and H. Minssen.....	931
Investigations on the phosphorous compounds of moor soils, B. Tacke.....	932
The changes which moor soils undergo under culture and manuring, G. Schliebs and H. Minssen.....	932
On the analysis of soil as a guide to its fertility, B. Dyer.....	933
The analyses of Jamaica soils, P. Watts.....	933
FERTILIZERS.	
The use and value of seaweed as manure, J. Hendrick.....	934
The starfish in Narragansett Bay, G. W. Field.....	935
Solubility of the phosphoric acid of Thomas slag and crude phosphates in upland moor soils as determined by the amount of free humus acids present, B. Tacke and H. Minssen.....	935
Utilization by plants of the phosphoric acid dissolved in soil water, T. Schloesing.....	936
Trial of phosphates, C. O. Flagg and J. A. Tillinghast.....	936
Tests of nitrogenous fertilizers on hoed plants, C. Dusserre.....	936
Observations regarding the relative assimilability of various forms of nitrogen upon an acid soil, limed and unlimed, H. J. Wheeler, B. L. Hartwell, and G. E. Adams.....	937
Observations in connection with a soil test continued for 8 successive years, H. J. Wheeler and J. A. Tillinghast.....	937
On the substitution of soda for and its value in connection with potash, H. J. Wheeler and J. A. Tillinghast.....	938
A study of the needs of certain Rhode Island soils, H. J. Wheeler, C. O. Flagg, and G. E. Adams.....	938
Five years' observations upon the growth of plants upon an acid upland soil, limed and unlimed, H. J. Wheeler and J. A. Tillinghast.....	939
On the action of burnt lime and marl on sandy soils, B. Tacke, H. Immendorff, A. Salfeld, and F. Wolff.....	940
Field experiments on upland moor soils and moor meadows by the Moor Experi- ment Station at Bremen during 1892-1897, B. Tacke, F. Gaaz, and H. Menk- haus.....	940
Pot experiments on moor soils at the Moor Experiment Station at Bremen, B. Tacke and H. Immendorff.....	941
FIELD CROPS.	
Report of the agriculturist, H. E. Stockbridge.....	951
A report of progress of investigations in the chemistry of wheat, G. L. Teller.....	943

	Page.
Summary of experiments with corn and wheat, 1898.....	945
Experiments with roots and forage crops, F. W. Rane	945
Forage crops, E. B. Voorhees and C. B. Lane	946
The lodging of grain, Julien and Dupont	947
The stooling of grains, B. C. Buffum	947
Trials with orchard grass, F. and K. Hansen.....	948
Influence of permanent grass culture on the nitrogen content of the soil compared with that of other crops, T. A. Tuxen	949
Field experiments with fertilizers in 1897.....	949
Third report on potato culture, I. P. Roberts and L. A. Clinton	950
Variety test of potatoes, C. O. Flagg, G. M. Tucker, and J. A. Tillinghast.....	951
Cultural experiments with potatoes, C. O. Flagg, G. M. Tucker, and J. A. Tillinghast	951
Further tests of seed potatoes grown one or more years in Rhode Island from northern-grown seed tubers, C. O. Flagg and J. A. Tillinghast	952
The potato crop in the rotations, C. O. Flagg, G. M. Tucker, and J. A. Tillinghast	953
External indication of an increase of solanin in potatoes, Schnell.....	953
Fertilizer experiments with potatoes, C. O. Flagg, G. M. Tucker, and J. A. Tillinghast	953
Trials with fish guano for sugar beets, P. Hansson.....	954
Fish guano <i>vs.</i> nitrate of soda for sugar beets and for barley, C. O. Hammargren.....	954

HORTICULTURE.

Report of the horticulturist, P. H. Rolfs.....	962
Garden lettuce and its cultivation, L. F. Kinney	956
Classification and description of the varieties of garden lettuce, L. F. Kinney.....	956
Some experiments in forcing head lettuce, S. A. Beach	957
Tea canning in Delaware, G. H. Powell	958
Ginseng—its nature and culture, H. Garman	958
Impressions of our fruit-growing industries, L. H. Bailey	959
Report of the Russian Apple Nomenclature Commission, August 30-31, 1898, N. E. Hansen	960
Chemical studies of Oregon fruits: Cherries, G. W. Shaw	961
Variety tests of strawberries, raspberries, and blackberries, W. Paddock	961
The European and Japanese chestnuts in the eastern United States, G. H. Powell	962
Distribution of seeds and plants, E. J. Wickson	963

FORESTRY.

Progress and effects of forest growing, R. W. Furnas	964
Preserving timber for estate and other purposes, D. F. Mackenzie.....	965
Cultivated shade and forest trees, B. C. Buffum.....	965
Measuring the forest crop, A. K. Mlodziansky	966

SEEDS—WEEDS.

Experiments on red clover seed, A. N. McAlpine.....	966
Studies in germination, V. Jodin.....	967

DISEASES OF PLANTS.

Report of the biologist, P. H. Rolfs.....	971
On the use of sulphur and sulphate of ammonia as preventives of potato scab in contaminated soils, H. J. Wheeler and G. E. Adams.....	967

EXPERIMENT STATION RECORD.

VOL. X.

No. 10.

The irrigation investigations in charge of this Office have already been referred to in the present volume of the Record (p. 201). The appropriation for this purpose having been increased at the recent session of Congress from \$10,000 to \$35,000, of which sum \$10,000 was made immediately available, these investigations are being further developed and the work in connection with them is being more thoroughly organized. The scope of the investigations has been more accurately defined in the last appropriation act. As there stated, funds are provided "To enable the Secretary of Agriculture to investigate and report upon the laws and institutions relating to irrigation, and upon the use of irrigation waters, with special suggestions of better methods for the utilization of irrigation waters in agriculture than those in common use, and for the preparation, printing, and illustration of reports and bulletins on irrigation; and the agricultural experiment stations are hereby authorized and directed to cooperate with the Secretary of Agriculture in carrying out said investigations in such manner and to such extent as may be warranted by a due regard to the varying conditions and needs of the respective States and Territories, and as may be mutually agreed upon."

The first bulletin prepared in connection with these investigations, which has recently been issued, contains a discussion of the irrigation laws which control the diversion and use of water from the Missouri River and its tributaries, by Prof. Elwood Mead, including papers on the water laws of Colorado and Nebraska, by the engineers of these States. Other bulletins of a similar character are in preparation.

For the present the investigations on the use of irrigation water will be largely confined to the determination of the actual amount of water used by successful farmers in different parts of the irrigated region on different soils and in the growing of different crops.

A temporary organization for the administration of these investigations has been effected by the appointment of Prof. Elwood Mead as irrigation expert in charge, and headquarters have been established at Cheyenne, Wyoming. It is hoped that some work may be done the present season in most of the States and Territories west of the Mississippi River in which irrigation is practiced to any considerable extent. Arrangements have also been made to aid the New Jersey

experiment stations in continuing their investigations, which have already attracted much favorable attention in the East.

As far as practicable the cooperation of the experiment stations will be sought in these investigations, and it is hoped that one result of this work will be that the stations will not only be able to develop their investigations relating to irrigation in the lines in which the Department will work under this appropriation, but also in other important lines involving operations by different divisions of the station. It is believed that by concentrating their efforts on problems based on the requirements of agriculture under irrigation, the stations in a number of States and Territories may materially enhance their usefulness.

It should be clearly understood that the irrigation investigations of this Department are intended to cover only a limited portion of the field of investigations relating to agriculture under irrigation which the stations and the different divisions of the Department may properly undertake. An effort will be made to mark out a line of work for these investigations which will give them a distinct place between the investigations of the Geological Survey relating to the topography and water supply of the irrigated region, and those of the different branches of the Department and stations which relate to the climate and plants of that region. Aside from the studies of the laws and institutions of communities in which irrigation is practiced, the irrigation investigations will have for their chief object the determination of the economic and profitable utilization of water in agriculture as it is supplied to the farmer through reservoirs, canals, and ditches. In these investigations, as in nearly all others relating to the complex science of agriculture, there will be many points of contact with investigations conducted under other auspices, and thus many opportunities for cooperative effort will be presented. With so large a field of operations and so great interests at stake, there will be abundant room for all the agencies now at work for the benefit of agriculture of the irrigated region to fully utilize all the means at their command. Besides the development of the irrigation investigations, the Department will, for example, continue studies of alkali soils, the native and cultivated plants and trees best adapted to the arid regions, and other related questions.

The people of that vast area of our country in which agriculture and the other industries are so largely dependent on the successful practice of irrigation, are to be congratulated that attention was more earnestly and successfully drawn to their needs during the recent session of Congress than ever before, and more ample provision than heretofore was made for studying the problems of agriculture in that region, through increased appropriations for the work of the Geological Survey and different branches of this Department.

INVESTIGATIONS ON THE METABOLISM OF MILCH COWS.¹

OSCAR HAGEMANN, PH. D.,

Professor at the Agricultural Academy, Poppelsdorf, Germany.

METABOLISM EXPERIMENTS WITH RUMINANTS.

When metabolism investigations are carried on with Herbivora—milk cows, for instance—other points must be considered which render the calculations still more complicated. The feeding stuffs are not as simple as in the case of Carnivora. They contain more amid compounds than flesh. The ether extract does not consist of fat alone, but of chlorophyll, wax, and similar bodies. Plant protein is not uniform in composition. While animal protein contains on an average 16 to 16.7 per cent nitrogen, there is a somewhat wider range in the case of vegetable protein. In addition to starch, the carbohydrates consist of pentoses, pentosans, gums, etc. Finally, vegetable feeding stuffs contain crude fiber, which is only in part digestible, and which is perhaps of paramount importance in investigations of this kind.

Nitrogen which is digested and is not excreted in the urine is assumed to be stored in the body, and this gain is best calculated as proteid, since, with the exception of a small part which remains in the growing tissue, the nitrogen is transformed into proteid. On the supposition that 4 per cent of the nitrogen in the lymph is nonalbuminoid nitrogen, and that the quantity of lymph is doubled by very abundant feeding, it is possible for the body to gain a considerable amount of amids without any change in the composition of the lymph. Similar reasoning might be applied to the muscles; but the ratio of the different nitrogenous bodies to each other in the muscles is not known with certainty, nor the proportion in which this nonalbuminoid nitrogen is eliminated. If, on the other hand, the tissues of the body lose water under intensive feeding, the body may possibly lose nitrogenous extractives, which appear in the urine and so introduce an error in calculating the gain of protein. However, such considerations are theoretical and have little practical value.

In determining the material digested, slight errors are introduced from the fact that the ether extract of the feces contains numerous bodies which were not originally present in the food, and the nitrogenous bodies in the feces have a different composition from those in

¹ Continued from p. 816.

the food. A more serious error, however, is caused by the crude fiber. This is not digested by the peptic and pancreatic ferments, etc., but by the action of bacteria, and, further, the digestion is not complete. The fermentation of other nitrogen-free bodies is induced by the same bacteria, and it is probable that protein is also broken down. At any rate the changes which take place are very complicated. Much light has been thrown upon this subject by Kellner's experiments with steers.¹ He found that for maintenance there was required 24,000 calories per day per 1,000 kg. live weight, or 1 calorie per kilogram per hour. In the case of steers fed hay the crude fiber of the feces has a higher carbon content and fuel value than that of the hay fed. It follows, therefore, that the crude fiber digested has a lower fuel value than that eaten. According to Kellner the fuel value of 1 gm. of pure digestible crude fiber furnishes 4.2196 calories, or, in round numbers, about the same as starch (4.18 calories per gram). Further, when hay is fed, the ether extract of the feces has a higher fuel value than the ether extract of the food. Therefore the fuel value of the digestible ether extract is also less than that of the food, being 8.322 calories per gram. Kellner gives the fuel value of the digestible nitrogen-free extract of hay as 4.232 calories per gram. These illustrations show that calorimetric analysis is much more delicate than the ordinary methods of proximate analysis.

In calculating the fuel value of protein it should be borne in mind, as stated above, that while practically all the amid nitrogen of the food is resorbed, a portion is oxidized in the body and excreted in the urine. Supposing this to have the same heat of combustion as asparagin (3.511 calories per gram), the fuel value of urea at least must be deducted from this in order to estimate its maximum nutritive effect. A gram of asparagin yields 0.454 gm. of urea ($\frac{60}{132}=0.454$), having a fuel value of 1.152 calories. A gram of asparagin (containing 0.212 gm. of nitrogen) would furnish 3.511 calories. This quantity, less 1.152, gives 2.36 calories as the available fuel value of 1 gm. of asparagin. These values are at best approximations, but the total error is not great, since such materials constitute only from 1 to 2 per cent of the total material metabolized.

According to Kellner's investigations, 3.5 calories per gram represents the physiological nutritive value of digestible organic material of meadow hay of medium quality when consumed by cattle. Such hay has the following percentage composition: Protein 1.393, fat 2.58, crude fiber 27.23, nitrogen-free extract 53.13, ash 7.06, carbon 46.16, and total nitrogen 1.6 per cent. According to Kellner, the total fuel value of the hay is distributed among its constituents as follows: Albuminoids 10.3, nonalbuminoid nitrogenous material 1.4, nitrogen-free extract 53.8, ether extract 3.6, and crude fiber 30.9 per cent. As noted above, cattle

¹ E. S. R., 9, p. 167.

require for maintenance 1 calorie per hour per kilogram of live weight. If a steer weighing 620 kg. is fed 8 kg. of meadow hay of the composition noted above, the ration would furnish 0.7 kg. of digestible protein and 6.6 kg. of digestible nitrogen-free material (crude fiber plus nitrogen-free extract plus fat multiplied by 2.4) per 1,000 kg. live weight. It is of the utmost importance to determine the amount of hay sufficient for maintenance, since hay serves as the basis of the ration.

Oat straw contains 85 per cent of dry matter, made up of 0.468 per cent of protein, 2.27 per cent of fat, 42.41 per cent of crude fiber, 6.6 per cent of mineral matter, 0.525 per cent of nitrogen, and 46.75 per cent of carbon. Using the data furnished by Kellner's experiments, it appears that a maintenance ration can not be made up of meadow hay and oat straw of the above composition without furnishing an excess of nitrogen-free material. In Kellner's experiments a steer weighing 612 kg. lost daily 91 gm. of protein and 102 gm. of fat when fed 3.45 kg. of meadow hay (dry matter) and 4.5 kg. of oat straw (dry matter). The coefficients of digestibility of dry matter of hay and straw were shown to be as follows:

Coefficients of digestibility of dry matter of hay and straw.

	Dry matter.	Organic matter.	Crude protein.	Pure protein. ¹	Nitrogen-free extract.	Fat.	Crude fiber.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Hay.....	64.9	62.4	6.1	6.7	37.3	1.6	17.4
Straw.....	55.1	52.5	.1	1.2	25.3	.6	26.5

¹Pure protein is calculated by assuming that for each 100 gm. of digestible dry matter 0.4 gm. of nitrogen due to metabolic products is excreted in the feces. Since the amid compounds are regarded as completely assimilated, it may be assumed that the remaining nitrogen of the feces is proteid nitrogen. Suppose that the food contained 633 gm. of protein, that 4.716 gm. of dry matter was assimilated, and that the dry matter of the feces amounted to 0.2547 gm., containing 1.795 per cent of nitrogen, or 45.72 gm. of nitrogen, the nitrogen due to metabolic products would be 18.86 gm. (47.16 × 0.4 = 18.86). The proteid nitrogen in the feces, therefore, would equal 26.86 gm. (45.72 - 18.86 = 26.86). This is equivalent to 168 gm. of protein. Therefore the food furnished 465 gm. of digestible protein (633 - 168 = 465).

Suppose, for instance, it is desired to calculate the quantity of hay and straw (containing 58.5 and 53.2 kg. of digestible nitrogen-free material, respectively) which would furnish 0.7 kg. of digestible protein and 6.6 kg. of nitrogen-free material. Let X gm. equal the hay fed and Y gm. the straw. Then 61 X + 1 Y = 700 gm. of crude protein, and 585 X - 532 Y = 6,600 gm. of nitrogen-free material. Solving the equations, X = 11.48 and Y = -0.2. In other words, on the supposition that hay and straw have the composition assigned to them above, a ration furnishing the desired quantities of protein and nitrogen-free material can not be made up from these feeding stuffs, since Y has a negative value. The straw contains too large a percentage of nitrogen-free material and too small a percentage of protein. Therefore the protein of the ration must be chiefly supplied by hay and the nitrogen-free material by straw, which will furnish an excess of the latter.

ENERGY REQUIRED FOR MASTICATION AND DIGESTION.

In calculating a ration for production for steers and cows it should be remembered (1) that a portion of the food must be utilized to supply energy for the labor of digestion, the amount of which is not definitely known, and (2) that fermentation takes place in the stomach and large intestines of Herbivora. The value of the latter factor may be calculated from the data furnished by Kühn and Kellner's experiments at Möckern. It was found that on an average 6.5 to 7 per cent of carbon from digestible crude fiber and nitrogen-free material was excreted as methan. According to Tappeiner's investigations cellulose adds water when it ferments, 100 gm. yielding 4.7 gm. of methan and 33.6 gm. of carbon dioxid, together with 33.6 gm. of acetic and butyric acid. These acids undergo combustion in the body, but, according to the investigations of Mallèrve only 75 per cent of their energy can be utilized. In round numbers, 100 gm. of cellulose, 4.7 gm. of methan, and 33.5 gm. of carbon dioxid contain 44.5 gm., 3.5 gm., and 9.1 gm. of carbon, respectively. In other words, in the example cited a total of 12.6 gm., or 28.3 per cent, of the carbon of digestible starch or cellulose is excreted in the form of gas, owing to the fermentation in the intestinal tract. If so much methan is produced by fermentation that its carbon content equals 6.7 per cent (average of 6.5 and 7 per cent) of the carbon of the total digestible nitrogen-free material (including crude fiber), it may be assumed that carbon dioxid was also formed in the same proportion as in Tappeiner's investigations; that is, for each 6.7 gm. of carbon of methan 17.4 gm. of carbon of carbon dioxid was produced. Therefore 24.12 per cent ($17.4+6.7=24.1$) of total starch and nitrogen-free extract has undergone fermentation. These calculations are not exact, since hydrogen is also formed in the intestinal tract. The amount for Herbivora is not known, but it is so small that the error introduced is insignificant.

The experiments made by Zuntz and the author with a horse may be cited to show the effect which the digestion of crude fiber exercises upon the consumption of oxygen and the production of carbon dioxid in respiration experiments. The horse excreted 4.7 gm. of methan and 0.2 gm. of hydrogen per 100 gm. of digestible crude fiber.

Effect of digestion of crude fiber on respiration.

	Carbon.	Hydrogen.	Oxygen.
	<i>Grams.</i>	<i>Grams.</i>	<i>Grams.</i>
100 gm. of crude fiber contains	44.44	6.18	49.38
4.7 gm. of methan contains.....	3.53	1.18
Difference.....	40.91	5.00	49.38
33.5 gm. of carbon dioxid contains	9.14	24.36
Difference.....	31.77	5.00	25.02
Deducting the hydrogen excreted.....20
Difference.....	31.77	4.80	25.02

For each 100 gm. of digested crude fiber completely oxidized in the animal body 149.99 gm. ($116.49 + 33.5 = 149.99$) of carbon dioxid (equal to 76.28 liters) is produced, and 98.1 gm. of oxygen (equal to 68.6 liters) is consumed from the air. The respiratory quotient is therefore $\frac{76.28}{68.6} = 1.112$.

The fuel value of the cleavage products of the crude fiber can also be calculated from the oxygen utilized and the carbon dioxid produced. One hundred grams of crude fiber has a fuel value of 418.5 calories; 4.7 gm. of methane would yield 62.7 calories (4.7×13.344 [fuel value of 1 gm.] = 62.7); 0.2 gm. of hydrogen would furnish 6.9 calories (0.2×34.6 [fuel value of 1 gm.] = 6.9; deducting the sum of 62.7 and 6.9 from 418.5 leaves in round numbers 349 calories. A total of 68.6 liters of oxygen would be used; that is, each liter of oxygen utilized for the combustion of digestible crude fiber produces 5.087 calories ($\frac{349}{68.6} = 5.087$). A correction should, however, be introduced for the

33.5 gm. of carbon dioxid and about 48 calories produced by fermentation. Under certain conditions this heat is as available for the body as that produced by the oxidation of materials in the tissues. Further, according to the investigations of Munk and Mallerve sodium butyrate and sodium acetate may be burned in the body, but the metabolism is also increased so that at best only four-fifths of their nutritive value is available. After deducting the 48 calories due to fermentation from the 349 calories per kilogram of digestible crude fiber mentioned above, there remain 301 calories. Assuming that only four-fifths of this is available, 100 gm. of digestible crude fiber yields for the body 240.8 calories. Using this value, 1 liter of oxygen from the inspired air would produce 3.51 calories ($240.8 \div 68.6 = 3.51$).

Energy is required for taking food into the mouth, chewing it, and for chewing the cud, and for all the processes of digestion. More or less energy is also required for the secretion of saliva and other digestive juices, and for taking up the digested material into the blood and lymph. The food must be moved through the intestinal tract, and finally the undigested matter must be excreted. Further, the labor of digestion causes increased activity of the heart and lungs. The resultant of all the energy expended is heat, and only a part of this heat is necessary for maintaining the body temperature. It is probable that when milch cows are fed an abundant diet so much heat is produced by the labor of digestion that a portion is radiated from the body unused.

It is plain, then, that a deduction must always be made from the total energy of a maintenance ration to cover the labor of digestion. The labor of chewing and digesting increases with increased amounts of crude fiber in the food. This has been shown by many experiments with cattle and horses. Zuntz and the writer found that with a horse the labor of chewing and digesting amounted to 260 calories per 100

gm. of crude fiber in the food. Values for milch cows are necessarily somewhat different, since the processes of digestion in ruminants and horses are dissimilar. In the case of a horse, protein, fat, and carbohydrates are acted upon by the digestive juices and absorbed in the stomach and small intestine. The cellulose and materials which have escaped digestion, because the walls of the cells in which they are inclosed have not been broken, finally reach that portion of the intestinal tract where fermentation takes place. The fermentation renders the crude fiber soluble, and further, when the cell walls are thus destroyed the nutrients which escaped digestion earlier can be reached by the digestive juices and absorbed. The act of moving the crude fiber through the long intestine to the point where fermentation takes place requires an expenditure of energy which may safely be assumed to reach 2.65 calories per gram of crude fiber in the food.

In the case of ruminants the food is retained for a long time in the first stomach and undergoes very active fermentation. This renders a large portion soluble and diminishes the amount of crude fiber, so that only a portion of the crude fiber must pass through the whole intestinal tract, the exact amount of which is not known. At all events, this step in digestion requires the expenditure of less energy than in the case of horses. On the other hand, chewing the cud requires a large amount of energy: so that it is not impossible that the total labor of digestion is fully as great in ruminants as in horses.

Cattle digest in round numbers 60 per cent of the crude fiber consumed. Using Kühn's data, Kellher has calculated that owing to fermentation 10 per cent of the digestible carbon is excreted in the form of hydrocarbons. Thus, of 100 gm. of crude fiber fed, 60 gm. is digestible, and 36 per cent, or 21.6 gm., undergoes fermentation. This has a fuel value of 52 calories ($\frac{240.8}{100} \times 21.6 = 52$). The total energy of the 38.4 gm. ($60 - 21.6 = 38.4$) of digestible crude fiber remaining is available. Since this is 4.18 calories per gram, the total would be 160 calories. In other words, 100 gm. of crude fiber in the food, of which 60 gm. is digestible, furnishes the body 212 calories ($52 + 160 = 212$). Since a horse requires 265 calories, this amount would be insufficient. Information is lacking for ruminants, especially milch cows, and special respiration experiments will need to be made in which rations containing large and small amounts of crude fiber are fed before statements such as the foregoing can be made with certainty. From what has been said it is probable that the labor of chewing and digesting food is less with ruminants than with horses, so that possibly the cleavage of crude fiber furnishes an amount of energy sufficient for digesting it.

The total labor of digesting fat in the case of man and dogs is not great. For protein and carbohydrates it is somewhat greater than for fat, amounting, according to the investigations of Magnus-Levy, aside from the labor of chewing, to about 9 per cent of the total energy of

the digested material. This is the value assumed for pigs fed rice. This value and other data can be calculated for swine by comparing Meissl's¹ work on the formation of fat in pigs when rice is fed with the values obtained in metabolism experiments with fasting swine.

One of the pigs weighed 71 kg. and was fed 2,000 gm. of rice daily. Ten liters of water and 10 gm. of salt were given in addition. The rice had the following percentage composition: Water 13.13, nitrogen 1.09, carbon 39.29, protein 6.81, fat 0.82, starch 78.76, crude fiber 0.09, and pure ash 0.39. The materials consumed in the food and excreted in the feces, urine, and respiratory products, and gained by the body per day are shown in the following table:

Metabolism experiment with pigs.

	Nitro- gen.	Pro- tein.	Fat.	Starch.	Crude fiber.	Carbon.	Ash.
	Grams.	Grams.	Grams.	Grams.	Grams.	Grams.	Grams.
Food consumed contained.....	21.8	136.2	16.4	1,575.2	1.8	785.8	19.8
Feces contained.....	3.7	23.2	4.3	7.0	1.5	19.6	4.1
Digested.....	18.1	113.0	12.1	1,568.2	.3	766.2	15.7
Urine contained.....	10.3	64.4				12.0	13.2
Remainder.....	7.8	48.6	12.1			754.2	2.5
Excreted in the breath.....						415.0	
Gained by the body.....	7.8	48.6	12.1			339.2	2.5

The protein, fat, and crude fiber digested contained in round numbers 69.2 gm. of carbon. The total digested carbon of the food was 766.2 gm. Therefore starch must have furnished 697 gm. ($766.2 - 69.2 = 697$). The 48.6 gm. of protein gained contained 25.8 gm. of carbon and the 12.1 gm. of fat contained 9.3 gm. of carbon. Since the total carbon gained was 339.2 gm., 294.1 gm. must have been obtained from starch, and must have been retained as fat. It follows that each gram of digestible carbon from starch furnished 0.422 gm. of carbon for the formation of fat ($\frac{294.1}{697} = 0.422$). There was excreted in the breath 21.4 gm. of carbon dioxid per kilogram of weight ($\frac{415.11}{3.71} = 21.4$),² which would contain 15.564 gm. of oxygen; 10.3 gm. of nitrogen was excreted in the urine, and 0.906 gm. of protein was broken down per kilogram of body weight ($\frac{10.3}{71} \times 6.25 = 0.906$). As noted above, this would require 1.23 gm. of oxygen ($1.358 \times 0.906 = 1.23$), and would produce 1.36 gm. of carbon dioxid ($1.507 \times 0.906 = 1.36$). There was stored up as fat 294.1 gm. of carbon from starch; therefore, the fat formed from starch per kilogram of live weight was 5.421 gm. ($\frac{294.1 \times 100}{76.54} \times 71 = 5.412$). As previously noted, when 44 gm. of fat

¹ Ztschr. Biol., 22 (1886), p. 84.

² CO₂: C = 44; 12 = 11.3. Therefore $C \times \frac{11}{3} = CO_2$.

was formed from starch, 51.07 gm. of carbon dioxid was produced at the same time. For this no oxygen from the air was required. The amount of carbon dioxid produced by the formation of 5.412 gm. of fat would therefore be 6.28 gm. If the 0.3 gm. of digestible crude fiber be neglected and the total nitrogen in the urine be regarded as derived from the cleavage of protein, since the rice fed contained practically no nonprotein nitrogen and the total protein content was small, the respiratory quotient of the pig may be calculated as follows: The oxidation of protein required 1.23 gm. of oxygen, producing 1.36 gm. of carbon dioxid. The fat formed from starch required no oxygen and produced 6.28 gm. of carbon dioxid. The oxidation of starch required 10.01 gm. of oxygen and produced 13.76 gm. of carbon dioxid. The total oxygen required was therefore 11.24 gm. and the total carbon dioxid produced was 21.40 gm. The respiratory quotient would be

$$\frac{21.40 \div 1.96633}{11.24 \div 1.43003} = \frac{10.88}{7.86} = 1.385.$$

A fasting pig weighing 141 kg. excreted 9.8 gm. of nitrogen in the urine and 217 gm. of carbon. At a weight of 71 gm. the pig would have produced more carbon dioxid, in the proportion of $\sqrt[3]{141^2}$: $\sqrt[3]{71^2}$, since the metabolism of small animals is intense and the cleavage (Stoffumsatz) is equal to the cube root of the square of the live weight. Of the 217 gm. of carbon in the expired air, 191.8 gm. came from the cleavage of fat, the cleavage of protein causing 9.8 gm. of nitrogen in the urine, which would have necessitated the excretion of 25.2 gm. of carbon in the breath as carbon dioxid ($217 - 25.2 = 191.8$). In the case of the pig weighing 71 kg. the oxidation of 2.15 gm. of carbon from fat and 0.282 gm. of carbon from protein furnished the energy expended per kilogram of live weight $\left(\frac{191.8 \times 27.1^1}{141} \times 17.15 = 2.15 \right)$.

As noted above, the oxidation of 1 gm. of carbon from fat liberates 12.4 calories. Therefore 2.15 gm. of carbon from fat would furnish 26.7 calories; and 0.282 gm. of carbon from protein would furnish 2.8 calories $\left(\frac{100}{41.1} \times 4.1 \times 0.282 = 2.8 \right)$. Therefore the energy per kilogram of live weight would be $26.7 + 2.8 = 29.5$ calories.

In the case of the pig fed 2,000 gm. of rice the oxygen utilized in the oxidation of protein was 1.23 gm., or 0.86 liters; that is, 0.906 gm. of protein was oxidized and 3.7 calories of energy was produced ($0.906 \times 4.1 = 3.7$). In the same experiment 10.1 gm., or 7 liters, of oxygen was required for the oxidation of starch, and this furnished 35 calories ($7 \times 5 = 35$). Further, 6.28 gm., or 3.2 liters, of carbon dioxid was produced as an accompaniment of the fat formed. As noted above, this furnished 3.68 calories ($3.2 \times 1.15 = 3.68$). The total energy liberated was therefore $3.7 + 35.0 + 3.7 = 42.4$ calories. The 3.7 calories furnished by the formation of fat played no part in the labor of digestion. Deducting this amount from the total (42.4) leaves 38.7 calories. The energy

¹ $27.1 = \sqrt[3]{141^2}$; $17.15 = \sqrt[3]{71^2}$.

produced by the fasting animal performing no labor of digestion was 29.5 calories. Therefore 9.2 calories ($3.87 - 29.5 = 9.2$) represents the labor per kilogram of live weight expended in digesting 28.17 gm. of rice (the amount consumed per kilogram of live weight). The digestible matter in 28.17 gm. of rice had a fuel value of 100.5 calories ($\frac{113}{71} \times 4.1 + \frac{1,568.2}{71} \times 4.18 + \frac{12.1}{71} \times 9.5 = 100.5$).

In the case of the soaked rice the labor of chewing can be left out of account. The labor of digesting rice which contains practically no crude fiber required an expenditure of energy equal to 9.2 per cent of the total energy of the digestible food.

In the absence of more accurate data it can be said that in the case of cattle crude fiber yields the same amount of energy that is required for its digestion. The labor of chewing and digesting the remainder of the food may be said to equal 10 per cent of the energy of the digestible nutrients; and further, 24.1 per cent of the nitrogen-free material undergoes fermentation.

According to Kellner's calculations, a basal ration for maintenance must furnish per 1,000 kg. of live weight 0.7 kg. of digestible protein, and 6.6 kg. of nitrogen-free material, including 2.1 kg. of crude fiber.

In a metabolism experiment made by the writer with a milch cow, the factors determined were the amount and composition of the food, urine, feces, and milk, as a respiration apparatus was not available. The details of the experiment were as follows:

CALCULATION OF RESULTS OBTAINED WITH COWS.

During the test the cow weighed on an average 440 kg. and consumed daily 5.4 kg. of wheat bran, 2 kg. of straw, 2.82 kg. of hay, 23.5 kg. of fodder beets, 30 kg. of water, and 30 gm. of salt. The preliminary period covered 15 days. The urine and feces were collected for 7 days. On an average 13.604 kg. of urine and 25.814 kg. of feces (equal to 4,419 kg. of dry matter) and 9.998 kg. of milk, containing 12.1 per cent of dry matter and 3.35 per cent of fat, were excreted per day.

The amounts of nutrients in the food and in the feces, with the coefficients of digestibility, are shown below:

Composition of food and feces and coefficients of digestibility.

	Dry matter.	Nitro- gen.	Crude protein.	Pure protein.	Fat.	Crude fiber.	Nitro- gen-free extract.	Pure ash and sand.	Pure ash.
	Gm.	Gm.	Gm.	Gm.	Gm.	Gm.	Gm.	Gm.	Gm.
Food consumed (5.4 kg. wheat bran, 23.5 kg. fodder beets, 2 kg. straw, 2.82 kg. hay, 0.03 kg. salt).	11,153	243.1	1,519	1,236	426	2,115	6,024	1,070	804
Feces excreted (4,409 gm. air-dry)	4,049	76.3	299	99	1,075	1,718	680	599
Food digested	7,104	166.8	937	327	1,040	4,306	390	405
Coefficients of digestibility.	Pr. ct. 63.7	Pr. ct. 68.6	Pr. ct. 75.8	Pr. ct. 76.8	Pr. ct. 49.2	Pr. ct. 71.5	Pr. ct. 50.4

The urine contained 96.2 gm. of nitrogen; the milk contained 50.9 gm. of total nitrogen, 47 gm. of albuminoid nitrogen, 335 gm. of fat, and 490 gm. of milk sugar. Deducting the nitrogen in the urine and milk from the amount digested shows that there was a gain of 19.7 gm. of nitrogen. As noted above, the cow digested 1,040 gm. of crude fiber, in addition to the protein, fat, and carbohydrates. According to previous statements, 924 gm. of crude fiber was required for maintenance ($0.44 \times 2,100 = 924$), therefore 116 gm. ($1,040 - 924 = 116$) of crude fiber was digested in excess of the amount required, and had no nutritive value because it was fermented, yielding carbon dioxide, water, and heat, the latter only being of use to the body. This necessitated an expenditure of 10 per cent of the total energy of digestion, on the supposition ordinarily made, and leaving out of account the fact that the energy derived from crude fiber merely covers the labor of chewing and digesting it.

On the basis of the nitrogen excreted in the urine, 577 gm. of protein ($96.2 \times 6.25 = 577$) was required for maintaining the animal. Deducting this amount from the total amount consumed leaves 422 gm. for milk produced and flesh gained. Some idea of the amount of nitrogen-free extract which was required for maintenance may be obtained from the following: The fuel value of digestible protein is 4.1 calories per gram, of starch 4.18 calories per gram. The two substances have practically the same value. An animal weighing 1,000 kg. requires 5.2 kg. ($0.7 + 6.6 - 2.1$ (crude fiber) $= 5.2$) of protein and nitrogen-free extract for maintenance. An animal weighing 440 kg. would therefore require $440 \times 5.2 = 2,288$ kg. As noted above, 577 gm. of protein was necessary for maintenance; therefore the nitrogen-free extract must have been equal to 1,711 gm. ($2,288 - 577 = 1,711$). The cow digested a total of 4,306 gm. of nitrogen-free extract. Deducting the 1,711 gm. necessary for maintenance, there remains 2,595 gm. Of this amount 24.1 per cent, or 625 gm., would be lost by the fermentation which takes place in the intestines, leaving 1,970 gm. of nitrogen-free extract available ($2,595 - 625 = 1,970$).

The labor of digestion would require 10 per cent of the 442 gm. of protein, 327 gm. of fat, 2,595 gm. of nitrogen-free extract, and 116 gm. of crude fiber (the amount previously calculated to be in excess of that required for maintenance). The amount of protein metabolized is shown by the excretion of nitrogen in the urine. Furthermore, as noted on p. 816, nitrogen-free extract can take the place of fat in the ratio of 44:107, *i. e.*, 2.4. Hence, the value of a ration can be calculated in terms of nitrogen-free extract, or "nutrients" in the sense in which Wolff used the term, giving $442 + (327 \times 2.4) + 2,595 + 116 = 3,838$ gm. of nutrients. Deducting 10 per cent of this amount, or 384 gm. from the 1,970 gm. of nitrogen-free extract, there would remain 1,586 gm., which may be assumed to be starch, sugar, or similar carbohydrates. Therefore the cow had at her disposal for milk production

442 gm. of protein, 327 gm. of fat, and 1,586 gm. of carbohydrates. The milk contained 318 gm. of protein, 335 gm. of fat, and 490 gm. of carbohydrates. The difference shows the material gained or lost by the body. That is, the body gained 124 gm. of protein and 1,096 gm. of carbohydrates, and lost 8 gm. of fat. The 1,096 gm. of carbohydrates would suffice for the formation of 465 gm. of fat ($1,096 \times \frac{1}{2.4} = 465$). Deducting the 8 gm. of fat lost, the total gain to the body was 457 gm. of fat. On the supposition that 30 gm. of protein is required for the growth of horns, hide, and hair, there remains 94 gm. of protein and 457 gm. of fat. Lean cow flesh contains 20.7 per cent of protein. The protein gained is therefore equivalent to 454 gm. of flesh.

As will be seen, a number of suppositions are necessary in these calculations, since no investigations have been made which cover some of the points—for instance, the energy employed in chewing and digesting food. That the calculations are substantially correct, however, is shown by the data which are available concerning the formation of fat in the animal body when an excess of carbohydrates is fed. Kellner has calculated from his own and Kühn's experiments that from each kilogram of digestible starch in excess of the amount required for maintenance 200 to 240 gm. of fat may be produced. As has been stated (p. 816), at most 44 gm. of fat could be formed from 107.13 gm. of starch; that is, 1 gm. of fat from 2.435 gm. of starch. Using this value, 411 gm. of fat would be formed from a kilogram of digestible starch instead of 200 to 240 gm. This difference is due to the labor expended in digestion and to the fermentation which takes place. As previously noted, it may be assumed that 10 per cent of the energy of a maintenance ration is expended in the labor of digestion.¹ According to the investigations of Magnus-Levy, little labor is expended in digesting fat, and considerable energy is required for the digestion of starch. When starch alone is consumed the labor of digestion may be assumed to be from 17 to 25 per cent of the total energy of the food. Assuming that it is 21 per cent and that 24.1 per cent of the total food undergoes fermentation, the amount of digestible starch available for the formation of 411 gm. of fat can be calculated as follows:

Let X = this quantity, then $X \times \frac{24.1}{100}$ = amount fermented, and $X \times \frac{21}{100}$ = expenditure for labor of digestion when 1 kg. of fat is formed from starch. The equation would therefore be $\frac{24.1}{100}X + \frac{21}{100}X + 1 = X = 1.82$ kg. of starch. It follows that 1 kg. of digestible starch would serve for the formation of 227 gm. of fat, or about the mean of the quantities given by Kellner.

¹Ten per cent is probably the minimum value, though this can not be said with certainty. Respiration or respiration calorimeter experiments are necessary before this can be determined accurately.

It should also be borne in mind in experiments with ruminants that the nitrogenous extractives serve as protectors of protein, and hence have a value greater than that indicated by their heat of combustion. Weiske, Meier under the writer's direction, and later Kellner have shown that with ruminants asparagin serves as a protector of protein. The most reasonable explanation is that the bacteria which cause fermentation in the intestinal tract use amid bodies as a nutrient in place of protein. If there is an abundance of amids present the bacteria use little protein, and when the supply of amids is limited protein which would have served for the needs of the body is utilized. The micro-organisms form protein from amid nitrogen by using it, together with carbohydrates, as a source of energy for the formation of cell plasma. They die and are eventually digested, and thus the body gains protein formed from amids.

Closely connected with the foregoing is the so-called depression of digestion. If a large quantity of starch or feeding stuffs rich in starch is added to the food of ruminants it has been observed that the digestibility of the nutrients, especially of protein and crude fiber, is diminished. If sufficient protein is added to the normal ration plus starch, the digestibility of the nutrients again becomes normal. This is undoubtedly explained by the fact that the bacteria in the stomach of ruminants serve to render the crude fiber soluble. When an abundance of starch is present they attack this, breaking down the starch molecules and leaving an equivalent quantity of crude fiber unchanged. In other words, many cell walls are not acted upon, and the digestive juices can not reach the cell contents. It is clear, therefore, that diminishing the digestibility of crude fiber must also diminish the digestibility of protein and fat. However, when protein is added to such a ration, or, as Kellner has recently pointed out, asparagin or ammonium acetate, the bacterial action is greatly increased and the digestibility of the crude fiber becomes normal.

CALCULATION OF RATION FOR A COW WITH CALF.

In calculating a ration for a pregnant milch cow, a number of suppositions are necessary. The ration for such a cow 4 months with calf, weighing 600 kg. and producing 12 kg. of milk daily, containing 4 per cent of protein, 5 per cent of milk sugar, and 3.5 per cent of fat, must be so adjusted that the general condition of the animal remains unchanged; that is, the ratio of fat to lean in the body, etc. The cow requires the nutrients for the formation of milk and for the unborn calf. On the supposition that, as the fetus increases in weight the milk yield diminishes, the amount of nutrients required by the fetus at any time—when 3 months old, for instance—can be calculated. A new-born calf weighs about 40 kg. The body contains about 26 kg. of water, 2.5 kg. of mineral matter, 1.5 kg. of fat, and 10 kg. of protein, including the proteid bodies in horn, hoofs, etc. This quantity of pro-

tein and fat is supplied by the maternal organism in 284 days, or at the rate of 35.2 gm. of protein and 5.3 gm. of fat per day. So far as is known the unborn calf itself metabolizes materials, and can not utilize the protein of the maternal organism directly. These materials undergo a loss during metabolism. It may be assumed that the maternal organism must supply about 20 per cent more protein and 10 per cent more fat than is actually required in order to make good this deficiency. That is, 42.2 gm. of digestible protein and 5.8 gm. of fat, or an equivalent amount of carbohydrates, is necessary for the formation of the 35.2 gm. of protein and 5.2 gm. of fat mentioned above. Although the fetus requires more material as it increases in size, the average requirements for the fourth month are the quantities given. The 12 kg. of milk produced would contain 480 gm. of protein, 420 gm. of fat, and 600 gm. of milk sugar. Therefore the cow would require $480 + 42.2 = 522.2$ gm. of protein for milk production and for the fetus, in addition to a sufficient amount of other material, which may be most conveniently expressed in terms of energy. The fuel value per gram of the protein under consideration is 5.711 calories; of the fat, 9.231 calories; and of the milk sugar, 3.952 calories. If a maintenance ration consists of 8 kg. of meadow hay of good quality, the materials added to make it a productive ration—for instance, peanut cake and fodder beets—must supply 522.7 gm. of digestible protein. Fodder beets contain very little protein, and without introducing much error it may be assumed that 50 per cent may be digested and assimilated. The protein of peanut meal contains 18.2 per cent of nitrogen (instead of the usual 16 per cent), therefore, 100 gm. of digestible nitrogen of peanut meal could be stored in the body or used for milk production only in the proportion $\left(\frac{100 \times 16}{18.2} = 87.9\right)$. Seventy-three per cent of the nitrogen of peanut meal is digestible. Assuming that peanut meal contains 7 per cent of albuminoid nitrogen, 100 gm. would supply the body with 28.1 gm. of available protein $\left(\frac{7 \times 16}{18.2} \times \frac{73}{100} \times 6.25 = 28.1\right)$. One hundred grams of fodder beets furnish 0.22 gm. of pure digestible protein. Assuming that X gm. beets and Y gm. peanut meal are fed, the equation would be $281Y + 2.2X = 522.2$. The fuel value of the total butter fat produced would be 3,877 calories ($420 \times 9.231 = 3,877$). The fat used for the formation of the fetus would be equivalent to 55 calories ($5.8 \times 9.5 = 55$), and the milk sugar produced would be equivalent to 2,371 calories ($600 \times 3.952 = 2,371$). Therefore, in addition to the protein mentioned above, the food must supply $3,877 + 55 + 2,371 = 6,303$ calories. If this energy is supplied by fat and carbohydrates the ration must also contain sufficient material to make up for the labor of digestion and for the losses by fermentation.

As previously mentioned, it may be assumed that the energy supplied by crude fiber is just sufficient for its mastication and digestion, while

chewing and digesting the protein, fat, and carbohydrates requires 10 per cent of their energy, and 24.1 per cent of the energy of nitrogen-free nutrients is expended in fermentation.

The amount of protein which the ration should furnish has been determined and, to simplify the calculation, the energy required for its digestion may be assumed to be furnished by starch. One hundred grams of peanut meal contains 6.5 gm. of digestible fat and 23.5 gm. of digestible nitrogen-free extract. Deducting 24.1 per cent nitrogen-free extract for the material which undergoes fermentation, the fuel value of the fat and nitrogen-free extract would be 136.2 calories ($6.5 \times 9.5 + [23.5 - 5.7] \times 4.18 = 136.2$); and 10 per cent of this should be deducted for the labor of digesting 28.1 gm. of protein, 6.5 gm. of fat, and 23.5 gm. of nitrogen-free extract. Expressed in terms of starch, the nutrients are equivalent to 67.2 gm. ($28.1 + 6.5 \times 2.4 + 23.5 = 67.2$ gm. starch). Ten per cent of this would be 6.72 gm. of starch, or, expressed in terms of heat, 28.2 calories. Therefore 100 gm. of peanut meal supplies the animal, in addition to protein, with nutrients having a fuel value of 108 calories ($136.2 - 28.2 = 108$).

In the case of fodder beets the calculation is simpler, since the fat content may be neglected. One hundred grams of fodder beets furnishes 8.3 gm. of digestible nitrogen-free extract and 2.2 gm. of pure digestible protein. The loss of nitrogen-free extract due to fermentation (24.1 per cent) is equal to 2 gm., leaving 6.3 gm., equivalent to 26.3 calories. The 2.2 gm. of protein and 8.3 gm. of nitrogen-free extract would furnish 43.9 calories, from which should be deducted 10 per cent, or 4.4 calories, for labor of digestion. Therefore the 100 gm. of fodder beets would furnish $26.3 - 4.4 = 21.9$ calories. As a matter of fact, the energy expended for digestion must be somewhat increased on account of the crude fiber in the beets. However, no account is made of the fat in the beets and the crude fiber in the peanut meal, so it may be assumed that these factors neutralize each other.

Taking into account what has been said, we have the following equation: $1,080 Y + 219 X = 6,303$. The equation previously given was $281 Y + 2.2 X = 522.2$. Solving the equations, $Y = 1.7$ and $X = 20.4$. That is, a ration of 8 kg. of meadow hay, 1.7 kg. of peanut meal, and 20.4 kg. of fodder beets is sufficient for a cow weighing 600 kg. 4 months with calf.

It is evident from what has been said that the composition of proteid bodies is a matter of great importance in determining their value in the animal body. It is to be regretted that practically nothing is known concerning the proteid bodies in coarse fodders and green feeding stuffs, and very little regarding those contained in grains and oil cakes.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

The albuminoid of wheat gluten, K. MORISHIMA (*Arch. Exper. Path. u. Pharmacol.*, 41 (1898), No. 1-5, pp. 315-354).—The author agrees with Osborne and Voorhees that the alcohol-soluble part of wheat gluten contains only 1 proteid (gliadin) instead of 3, as stated by Ritthausen. The latter's preparations contained phosphorus, and this is true of the preparations of the alcohol-insoluble proteid glutenin. It was thought that possibly this phosphorus might occur as an impurity; and the author attempted to determine whether proteids of wheat gluten could be prepared entirely free from phosphorus. This work led him to the conclusion that gluten contains only a single proteid, to which he gives the name artolin.

In his investigations gluten was prepared from the finest commercial Hungarian wheat flour, using hydrant water with a considerable lime content for washing out the starch, since, as he says, the employment of distilled water gives a gluten which can not be kneaded into a compact mass. The gluten was dissolved in a weak potassium hydrate solution, the cloudy solution decanted from the sediment, and precipitated with hydrochloric acid, sufficient acid being added to give the solution a strength of 1 per cent, to aid the filtration. The precipitate was collected on bolting cloth, thoroughly washed with 1 per cent hydrochloric acid, and treated with sufficient alcohol to give a strength of 70 to 80 per cent with the water retained by the precipitate. The clear solution was filtered off after a few days and the residue treated with more alcohol, this being repeated until only a very small residue remained. These alcoholic solutions of the gluten were united, 95 per cent alcohol added until cloudy, and then precipitated with ether. The precipitate, consisting of hydrochloric-acid artolin, was washed with 95 per cent alcohol, and then dissolved in the smallest possible amount of water, to which a little alcohol has been added, gentle heat being employed. Where necessary the precipitate was purified by repeated solution in alcohol and reprecipitation. Finally it was freed from water by standing in strong alcohol and by drying in a vacuum over sulphuric acid.

The artolin prepared in this way was nearly free from ash and was entirely free from phosphorus, although it contained a constant amount of chlorine which could not be removed. From analysis of 4 preparations from 2 kinds of flour the author gives the formula for free artolin as $C_{135}H_{290}N_{50}SO_{50}$, and for the hydrochloric-acid-artolin, $C_{135}H_{288}N_{50}SO_{50} \cdot 2HCl$.

This artolin, it is claimed, constitutes the principal part of gluten. It corresponds in general to gliadin, although it differs somewhat in composition and in physical properties. Its properties are described.

Another substance, containing phosphorus, was obtained from the small residue insoluble in alcohol, mentioned above. This body was present only in small amount, and is thought to be a second constituent of gluten. The substances gliadin, mucedin, gluten fibrin, glutenin, and gluten casein are believed to be mixtures of artolin and this phosphorus body united with a base, as lime. The author is not certain whether or not the phosphorus body is an albuminoid, but will investigate it further.

The inversion of sugar by salts, L. KAHLLENBERG, D. J. DAVIS, and R. E. FOWLER (*Jour. Amer. Chem. Soc.*, 21 (1899), No. 1, pp. 1-23, fig. 1).—The method of experimentation is described, and the results are given for trials with salts of aluminum, manganese, zinc, cadmium, nickel, copper, mercury, iron, and ammonia.

“The main results of this investigation may be summed up briefly as follows:

“(1) The freezing point method may be successfully employed in determining the speed of the inversion of sugar.

“(2) When the metals are arranged in a series according to the speed with which their salts of the same acid radical invert sugar, it appears that the order is similar to that of the electrochemical series. Aluminum forms a notable exception. In spite of the high position of this metal in the electrochemical series, its salts invert sugar more rapidly than those of any other metal thus far tested.

“(3) Chlorides invert sugar more rapidly than sulphates, because the ironizing tendency of chlorine is greater than that of the sulphuric radical.”

The rapid detection of perchlorate in nitrate of soda, P. NYSSSENS (*Bul. Assoc. Belge Chim.*, 12 (1898), No. 5-6, pp. 187, 188; *abs. in Chem. Centbl.*, 1898, II, No. 26, p. 1281).—Into a test tube containing the nitrate of soda to be tested, introduce 15 cc. of a saturated solution of potassium perchlorate. Keep the test tube in a vessel of water at ordinary room temperature and shake from time to time. All chlorates, sulphates, and other salts usually present in commercial nitrate of soda, with the exception of potassium perchlorate, are dissolved in the saturated perchlorate solution. Filter the solution and wash the residue once with a saturated perchlorate solution and then with 85 per cent alcohol. If perchlorates are present the characteristic crystals will be found in the residue on the filter and the amount may be determined by the usual methods, or by weighing the residue and deducting the weight of insoluble impurities as determined in another portion of the sample.

On the volatile and insoluble fatty acids in butter, R. HENRIQUES (*Chem. Rev. Fett u. Harzind.*, 5 (1898), No. 9, pp. 169-172; *abs. in Analyst*, 21 (1899), Jan., p. 7).—The author investigated several samples of pure butter unusually low in volatile fatty acids, with the idea of devising a method for distinguishing these butters from mixed butters. The method is based on the differences in the actual quantity and the average molecular weight of the volatile and nonvolatile fatty acids. The results, however, show that butters with a normal Reichert-Meissl number contained 5 to 6 per cent volatile fatty acids, those with an abnormal 4 to 5 per cent, the average molecular weight of which varied from 93.3 to 99.8; hence the results have but a negative value for analytical practice. With regard to the insoluble fatty acids, the Hellner number ranged between 86.5 and 89.1 for normal and 88.96 to 90.68 for abnormal butters; but a difficulty arose in the estimation of the average molecular weight in that the values found on drying at 105 to 110° C. (viz, 267 to 270) differed from those (256.3 to 263) obtained when the drying was effected at the ordinary temperature in a vacuum desiccator.

The author, however, considers that assuming butter to contain a large proportion of oleic acid, the above figures indicate that a considerable amount of an acid of lower molecular weight than palmitic acid is present; and that by isolating this acid and separating the unsaturated from the saturated acids it is not improbable, provided the assumption of a low average molecular weight for this undetected acid be found correct, that the presence of extraneous fats in butter may be discovered by the relatively higher molecular weight of the saturated acids they contain.

Chemical division of the Rhode Island Station, H. J. WHEELER, (*Rhode Island Sta. Rpt.* 1897, pp. 166-176).—This is a summary account of the work of the chemical division of the station during 1897 in the following lines: Fertilizer inspection, studies of methods of analysis, special chemical investigations, field and pot experiments, experiments in culture under glass, etc.; and analyses of miscellaneous materials, including mixed fertilizers, muriate of potash, calcined sulphate of potash and magnesia, carbonate of potash and magnesia, carbonate of potash, nitrate of potash, carbonate of soda, dried blood, dissolved boneblack, dissolved bone, double superphosphate, dissolved phosphatic rock, Thomas slag, sulphate of ammonia, waste lime from soda-ash works, lime, magnesium sulphate, floats, fine ground bone, tankage, and water.

Third International Congress of Applied Chemistry (*Jour. Amer. Chem. Soc.*, 21 (1899), No. 1, pp. 73-102).—This is a brief report of the congress held in Vienna, July 27 to August 4, 1898. It gives a list of the papers read, with abstracts in some cases and notes on the discussion; and an account of the excursions and scientific visits, with short descriptions of the institutions and laboratories visited.

Glycollic acid, one of the acids of sugar cane, E. C. SHOREY (*Jour. Amer. Chem. Soc.*, 21 (1899), No. 1, pp. 45-50).—In a previous paper (E. S. R., 9, p. 721) the author

announced the discovery of glycozell as the principal amid constituent of sugar cane. He now announces the discovery of glycollic acid in sugar cane, and describes its separation, properties, etc., and discusses its bearing in relation to sugar manufacture and sugar chemistry, as well as its physiological significance in the plant.

The combinations of carbon in humus substances, G. ANDRÉ (*Compt. Rend. Acad. Sci. Paris*, 128 (1899), No. 8, pp. 713-716).—In previous articles (E. S. R., 10, p. 830) the author has reported investigations on the form of nitrogen in humus. This article discusses the form of carbon in these substances as determined by methods similar to those employed in the investigations of the nitrogen compounds.

The nitrogenous compounds in fungi, E. WINTERSTEIN (*Ztschr. Physiol. Chem.*, 26 (1899), No. 5, pp. 438-441).—In this article, which is a preliminary communication, the author reviews the literature of nitrogenous constituents of fungi, and briefly reports a study of the nitrogenous material extracted from *Boletus edulis* and *Agaricus campestris*.

Is ferric chlorid volatilized when evaporated from acid solutions? L. L. DE KONINCK (*Bul. Assoc. Belge Chim.*, 13 (1899), No. 1, pp. 5-10).—The author, after reviewing the work of Fresenius and Vogel, concludes as the results of his own labors that "under the ordinary conditions of analysis, the quantity of iron lost in this way may be neglected."—H. SNYDER.

A critical review of the methods of analysis of fats, A. LEMOINE (*Bul. Assoc. Belge Chim.*, 13 (1899), No. 1, pp. 26-39).—A table is given showing the "saponification index" (Koettstorfer number) and the percentage of carboxyl and oxycarboxyl of fatty bodies. The author contends that it is more scientific to adopt, in place of "potash number," the terms, carboxyl for actual acidity, and oxycarboxyl for "latent" acidity of the fatty body.—H. SNYDER.

The identification and reaction of saccharose, dextrose, levulose, and maltose, A. GAWALOWSKI (*Pharm. Post*, 1898, p. 380).

The chemical and bacteriological analysis of drinking waters, F. BAUCHER and G. DOMMERQUE (*Traité pratique d'analyse chimique et microbienne des eaux d'alimentation*. Paris: Imprimerie Levé. 1898; rev. in *Jour. Hyg.*, 23 (1898), No. 1157, p. 564).

Methods for the bacteriological examination of water, W. HESSE and NIEDNER (*Ztschr. Hyg.*, 29 (1898), p. 454; abs. in *Chem. Ztg.*, 23 (1899), No. 12, *Repert.*, p. 35).

On the determination of the value of waxes, A. HEUPEL (*Ztschr. Angew. Chem.*, 1899, No. 8, pp. 171, 172).

Temperature correction tables for picnometer measurements, P. FUCHS (*Ztschr. Angew. Chem.*, 1899, No. 2, pp. 25-27).

New laboratory apparatus (*Ztschr. Angew. Chem.*, 1899, No. 8, pp. 173-175, figs. 6).—Describes (1) an apparatus for the volumetric determination of hydrogen, methane, and nitrogen in gas mixtures by fractional combustion with copper oxid, (2) a safety sand bath, (3) an apparatus for the quick determination of the specific gravity of gums, and (4) a universal holder.

An aerometer with temperature correction scale, P. FUCHS (*Ztschr. Angew. Chem.*, 1899, No. 1, pp. 15, 16, fig. 1).

A new automatic pipette with reservoir, H. GÜCKEL (*Ztschr. Angew. Chem.*, 1899, No. 1, p. 10, fig. 1).

BOTANY.

Grass culture in Iceland, P. TEILBERG (*Ber. Andra Nord. Landtbr. Kongr., Stockholm, 1897, I, pp. 310-312; II, App. 8, pp. 27*).—This article gives a description of the topography, meteorological conditions, soils, vegetation, and agricultural resources of Iceland, together with agricultural statistics and an enumeration of the most important grasses and other meadow plants. The pasture grasses of Iceland

consist mainly of *Festuca rubra*, *F. ovina*, *Agrostis vulgaris*, *Poa pratensis*, *P. casia*, *Anthoranthum odoratum*, *Aira caespitosa*, and *Alopecurus geniculatus*. *Trifolium repens* and *Alopecurus geniculatus* occur in moist places. *Achillea millefolium* is quite abundant on the meadows, and a large number of other plants, especially sedges and the coarser grasses, are frequently found in small quantities. Other plants frequently found on the meadows are *Carex vulgaris*, *C. cryptocarpa*, *C. chordorhiza*, *C. variiflora*, *C. ampullacea*, *C. limosa*, *C. dioica*, *C. canescens*, *Menyanthes trifoliata*, *Eriophorum angustifolium*, *E. capitatum*, *Juncus triglumis*, *Scirpus caespitosus*, *Vaccinium uliginosum* and *Betula nana*. "Iceland is the land of the Cyperaceæ and the coarsest species of grasses, but cattle which through generations have become accustomed to the coarse food do well on it."—F. W. WOLL.

The seeds and seedlings of some Amentiferæ, W. W. ROWLEE and G. T. HASTINGS (*Proc. Amer. Assoc. Adv. Sci.*, 17 (1898), p. 136).—The authors state that compared with other groups, the seeds and seedlings of this group have not been observed to any extent. This fact led them to a series of studies, and their conclusions, brielly stated, are as follows: In the walnuts and hickory nuts the cotyledons correspond to the valves of the nut and are deeply two-lobed. The divisions of the embryo resembling cotyledons are each made up of valves of the cotyledons. The seeds of hickory will germinate without frost action, while those of walnut require it. The taproot of all these seedlings is very thick in young plants and very long in older ones. In the case of chestnuts and oaks the shell is split by swelling of the cotyledons in germination. In the species of oak studied the leaves of the seedlings were very much alike, being neither very deeply cut nor lobed. The beech is said to be the only one of all the genera examined in which the hypocotyl lengthens or the cotyledons become aerial.

Temperature of plants, F. SCHLEICHERT (*Naturw. Wechschr.*, 13 (1898), pp. 469-472; *abs. in Jour. Roy. Micros. Soc.* [London], 1899, No. 1, p. 57).—Observations on the temperature of trunks and leaves are reported, from which it appears that the temperature of the interior of the trunk of *Paria rubra* at a depth of 12 cm. below the surface was dependent on the temperature of the surrounding air, attaining its maximum and minimum later than that of the atmosphere. It is influenced to a less extent by the temperature of the soil and of ascending currents of water, as well as by the degree to which the leaves are exposed to direct sunlight. The temperature of leaves was found in some cases to be slightly lower (0.7° C.) than that of the surrounding air, owing to transpiration. In other cases, such as thick-leaved plants of aloes and cactus, when exposed to bright sunlight the temperature was considerably higher; when the air temperature was 20° that of the interior of the leaf was 28.5° C. This difference is said not to be due to the development of heat in the leaf, but to the absorption of heat through the thick mass of leaf or stem.

Movement of plant food before the fall of the leaf, E. RAMANN (*Ztschr. Forst u. Jagdw.*, 30 (1898), No. 3, p. 157; *abs. in Gard. Chron.*, 3, ser., 21 (1898), No. 610, pp. 183, 184).—The author states that previous investigations on this subject have usually been undertaken with beech leaves, which are extremely liable to variation in structure and composition in proportion to the amount of light they receive. In order that his results might admit of comparison with those of other investigators, his experiments were conducted with leaves of beech, oak, hornbeam, and hazel. Given quantities of the leaves of these species were collected at stated periods from June to September, weighed, counted, their superficial area, average size, and weight ascertained, and their composition determined by careful analysis. An analysis was also made of the ash of 100,000 sq. cm. of leaf.

It was ascertained that the soluble mineral substances reached a maximum about the beginning of June and remained unaltered until autumn. This was especially true of potash and nitrogenous matter almost without exception. Phosphoric acid appeared to show a slight increase toward autumn, perhaps the result of separation of insoluble compounds. The insoluble forms, such as lime, either increase until the period of assimilation is finished or they attain a maximum proportion, after which they remain stationary, as is the case of silicic acid. No return movement of material could be noticed up to the end of September, and as long as assimilation was continued there was no occasion for such movement. In November green and autumn-tinted leaves were gathered from the same branches, the tinted leaves still being turgid and showing some trace of chlorophyll. Testing these leaves with iodine showed that the green leaves were still rich in starch, while the yellow ones had little trace. The detailed results of the analyses show that tinted leaves of beech gave a decrease in the phosphoric acid and nitrogenous substances, a strong increase in silicic acid and potash, and a material increase in lime. In the oak phosphoric acid and nitrogenous matter decreased in the tinted leaves, potash remained about the same, while lime and silicic acid were nearly double the quantity found in the green leaves. In tinted leaves of hornbeam there was a decrease of potash, phosphoric acid, and nitrogenous material and a moderate increase in silicic acid. The leaves of the hazel showed the nitrogenous matter strongly decreased, potash slightly reduced in quantity, and phosphoric acid remaining about the same. Lime and silicic acid were greatly increased.

Summing up the results of his investigations, the author concludes that during the period of growth in the beech and probably other trees, the proportion of mineral substances in the stem and leaves becomes about equal early in the season and remains unaltered until the growing season is finished. Substances which are partly separated in the insoluble form gradually increase in the leaves. With the death of the leaves a considerable movement of mineral substances takes place, the nitro-

enous substances and phosphoric acid returning to the tree probably in connection with the separation of insoluble albuminoids. Lime and silicic acid move into the leaves, and potash may either remain stationary, return to the stem, or move into the leaves, according to circumstances.

Starch distribution as affected by fungi, B. D. HALSTED (*Proc. Amer. Assoc. Adv. Sci.*, 17 (1898), pp. 108, 109).—The author has investigated starch distribution in leaves as affected by fungi, and has examined leaves of *Agrimonia mollis* affected by *Peronospora potentilla*, of *Amphicarpaea monoica* infested with *Synchytrium decipens*, leaves of *Amarantus retroflerus* attacked by *Cystopus bliti*, and mandrake leaves affected with *Puccinia podophyllii*. The leaves studied were placed in a 50 per cent solution of alcohol to remove the chlorophyll and then passed to a weak solution of iodine. In a few hours, if the leaf is thin, the starch responds to the iodine test and is located by the blue color. In the cases of the leaves just mentioned the starch was present either in the discolored spot or immediately around it; and this distribution was very striking in the mandrake leaves, the starch being very abundant in well-defined areas. None was met with beyond the small veins that served as the boundaries of the infested portions. Smutted corn leaves showed much starch in the bullate portions characteristic of the affected parts.

Stems infested with fungi showed the presence of starch, as was shown in the case of the leaves. Radish stalks which had become hypertrophied, when sliced and placed in the iodine solution became blue, while similar sections taken from a healthy portion of the same stem showed but a very small amount of starch. Similar results were also obtained with stems of purslane. Ordinarily the red cedar stem contains but little starch, but the galls made by the *Gymnosporangium macropus* abounded in it. Galls on peach roots were gorged with starch, and turnips affected with the club-root fungus carry a large amount of starch, while healthy tissue is comparatively free from it. In like manner the tubercles of leguminous plants contain much starch, while the roots bearing them are comparatively free from it.

Poisonous properties of wild-cherry leaves, F. W. MORSE and C. D. HOWARD (*New Hampshire Sta. Bul.* 56, pp. 112-123, figs. 6).—In 1894 and again in 1897 a number of cases of poisoning of cattle were reported to the station. An examination of the stomachs showed no trace of metallic poisoning, but the symptoms, together with statements relating to the feeding of the animals, seemed to indicate that death was caused by eating wild-cherry leaves.

In order to obtain some definite information on the amount of prussic acid yielded by different species of cherry leaves, investigations were carried over portions of 2 summers on the wild black cherry, choke cherry, wild red cherry, wild yellow plum, and the dwarf cherry. The first 2 species are quite common throughout the State. Investigations

showed that the leaves of the wild plum, as well as those of the cultivated varieties, seemed to be harmless. The least poisonous of the 3 principal species is the wild red cherry (*Prunus pennsylvanica*). The second species (*P. virginiana*) is more common than the former and is also more poisonous; but by far the most dangerous variety occurring in New England is the wild black cherry (*P. serotina*).

The authors state that "the poisonous property of all species of cherry leaves is due to hydrocyanic acid, popularly known as prussic acid. This compound does not exist as such in the growing leaf, but is derived from a class of substances called glucosids, of which amygdalin is the type peculiar to the cherry. This, or a closely allied body, is to be found not only in the leaves and bark, but especially in the stones of cherries, peaches and plums, and the seeds of the apple. By the action of moisture, and a vegetable ferment called emulsin which exists in the plant, a complex chemical reaction takes place that begins in the leaf the moment connection with the circulatory system is cut off. The 3 products of this reaction are hydrocyanic acid, grape sugar, and benzaldehyde or bitter-almond oil."

The popular opinion that the leaves of the wild cherry are poisonous only when in a wilted condition is proved to be erroneous, since analyses showed that freshly cut leaves yield nearly as much acid as the wilted leaves when calculated to the fresh material taken. On the the other hand thoroughly dried leaves yield a small amount of acid and as ordinarily dried, in the hay field, they might be capable of generating a considerable quantity of poison. A tabulation is given in which the analyses of the different species is shown. The average of 11 analyses of 100 gm. of wild cherry leaves gave 212 mg. of prussic acid. When wilted the amount was found to vary somewhat with the degree of wilting, varying from 244 to 294 mg. per hundred grams of weight after drying. Leaves dried to 42 per cent of their original weight contained 71 mg. of prussic acid to 100 gm. of leaves.

Marked differences were noticed between the quantity of acid obtained from the leaves wilted in bright sunlight and those wilted in darkness, the former producing the larger amount. The condition and stage of growth of the leaves has a marked influence on the amount of hydrocyanic acid occurring in them. The larger, tenderer, and more succulent the leaves the greater the amount of acid which can be developed from them. Young shoots which come up where they have been frequently mowed off are much the richest in poison, while the woody leaves from full-grown shrubs or trees contain so little acid as to render them nearly harmless. Ten analyses of the leaves of the wild black cherry from isolated shoots contained 212 mg. per hundred grams of freshly cut leaves, while similar leaves from full-grown trees contained only 106 mg.

The symptoms of poisoning and the toxic dose of prussic acid are given. The following are the authors' conclusions:

"The leaves of the wild black cherry are the most poisonous of the 3 species investigated, though all are dangerous.

"Both the wilted and fresh leaves are poisonous, while the dried are to be regarded with suspicion.

"Vigorous, succulent leaves from young shoots, which are the ones most liable to be eaten by cattle, are far more poisonous than the leaves from a mature tree or stunted shrub.

"Leaves wilted in bright sunlight to about 75 per cent original weight, or until they begin to appear slightly limp and to lose their gloss, yield the maximum amount of prussic acid."

Concerning proteid synthesis in green plants, B. HANSTEEN (*Christiania Videnskabs Selskabs Skrifter*, 1898, I, No. 3; *abs. in Chem. Ztg.*, 22 (1898), No. 95, *Repert.*, p. 291).—The conclusions of the author, as shown by the abstract, indicate that light is not essential to proteid formation in phanerogams. This important function may take place in the dark under a number of conditions, namely, when the living cells are supplied with asparagin, glutamin, ammonia, ammonium chlorid, or ammonium sulphate and grape sugar, or when they are supplied with asparagin, ammonia, ammonium chlorid or ammonium sulphate with a reducing sugar, and when given ammonia or glyco-col in connection with cane sugar and, possibly, with other non-reducing sugars. The chemical nature of the carbohydrates present is a matter of considerable importance in the transformation of amids and amido acids into proteids, since proteid formation is dependent upon the presence of carbohydrates and nitrogen compounds. The various forms of nitrogenous compounds are not equally efficient in proteid synthesis. The best source of nitrogen has been found to be ammonia, followed by others in the following order: Ammonium chlorid, ammonium sulphate, glyco-col, asparagin, and ghtamin. Leucin, alanin, kreatin, potassium and sodium nitrate are not adapted to proteid synthesis in *Lemna minor* when grown in the dark, and the author states that it is probably true of other phanerogams. The alkali chlorid present has a regulatory influence on the active protoplasm, in that the chlorids present tend to regulate the production of proteids and the consumption of carbohydrates in the proper proportion in the plant. An abnormal amount of carbohydrates formed will be at the expense of proteid production, and *vice versa*. When one fertilizes with potassium chlorid, the amount of chlorid will determine whether the production of plant material will proceed normally or not and this amount varies with different plants.

Formation of albuminoid substances in plants by the reduction of nitrates, A. HÉBERT (*Ann. Agron.*, 24 (1898), No. 9, pp. 416-440).—The author gives a historical review of considerable of the literature relative to the formation of albuminoids, and states various theories which have been advanced by Loew, Victor Meyer, E. Schulze, Bach, Gantier, and others. A brief statement is given concerning the author's investigations on the presence and localization of hydrocyanic acid in certain plants. None were found present in a number of aroides examined, while slight quantities were found in different parts of *Ribes* spp. Hydrocyanic acid is said not to occur to any appreciable extent in the horticultural varieties of rose.

Special studies with *Aquilegia vulgaris* were made to localize hydrocyanic acid which exists in that plant. None was found present in the roots, petals, or stamens. In the leaves there was from 1 to 2 mg. per hundred grams, in the stem 3 to 6 mg., and in the buds and ovaries about 10 mg. per hundred grams of fresh material. From this it appears that only those organs of the plant containing chlorophyll are able to produce hydrocyanic acid.

From his own experiments and those reviewed, the author concludes that nitrates which are reduced in plants, pass through a hydrocyanic acid state, and this generally takes place in parts of the plant where assimilatory production of formic aldehyde predominates. It appears well established that formic aldehyde possesses great power to form combinations and polymers, and these are closely related with the glucoses, pentoses, and hexoses. The cyanogen derivatives are equally susceptible of combination, passing through various forms which give methylamins. It has been shown by Kilani that all the sugars in plants are capable of combining with hydrocyanic acid to form nitrites. It seems probable that hydrocyanic acid formed in plant cells enters into combination with formic aldehyde, giving more or less complex nitrogenous compounds, as amids, amins, and nitrites, the fundamental products for the hydration of albumen.

The influence of Nitragin on the growth of various legumes, M. MAERCKER and H. STEFFECK (*Abs. in Chem. Centbl.*, 2 (1898), No. 18, p. 938).—Various legumes were grown in pots with sterilized and unsterilized soil. The kinds of soil used were light loamy sand, humus loam, and pure sand. Each pot contained 6 kg. of soil, which was fertilized with 1 gm. of phosphoric acid in the form of Thomas slag, 1 gm. of potassium sulphate, 1 gm. of potassium chlorid, 1 gm. of magnesium sulphate, and 10 gm. of calcium carbonate. The inoculation was effective on sterilized soil in nearly all cases. With blue lupines the effect was most marked, while with alfalfa no effect was noticeable. The percentage of nitrogen increased with the yield, and the increase of accumulated nitrogen was found exclusively in the parts of the plants above ground.

Experiments with Nitragin, A. P. AITKEN (*Trans. Highland and Agr. Soc. Scotland*, 5. ser., 10 (1898), pp. 299-305).—The author has previously reported a series of experiments conducted under his direction with this substance (E. S. R., 7, p. 906). Supplies of Nitragin for clover, beans, and vetches were distributed to a large number of farmers with directions for applying to the soil. In the different experiments which are summarized the results secured from plats with and without Nitragin varied so little as to be practically within the limits of error.

“The conditions under which we are warranted in expecting that Nitragin will be of service to agriculture are the absence of sufficient nitrogenous matter in the soil capable of producing a full leguminous crop, and the absence of the *Bacillus radicicola*, which enables the plant to obtain a sufficient supply of nitrogen from the atmosphere. It is doubtful if these two conditions will be found to coexist in any soil under rotation in this country.”

A brief note is appended concerning Alinit, in which the author states that the proof that this substance can enable cereals to assimilate free nitrogen is far from complete, and the claims that it will render the application of nitrogenous manures for the growth of cereals unnecessary are at least immature.

On the use of Alinit in the cultivation of cereals, L. MALPEAUX (*Ann. Agron.*, 24 (1898), No. 10, pp. 482-490).—The author reviews a series of experiments conducted with wheat, barley, and oats grown in pots and in the open field to test the effect of additions of Alinit in increasing their yield. Results seem to show that when conditions are favorable for the development of *Bacillus megatherium* (that is, when the soil is overrich in organic matter) Alinit proved very efficacious, but when the conditions were unfavorable for the development of the organism its effect amounted to nothing. It was found that in sterile siliceous soils Alinit was without any appreciable effect on the production of these cereals. The fixation of atmospheric nitrogen appeared to be through the destruction of the organic material and in soils rich in humus the intervention of this organism would prove advantageous. When added to soils of ordinary fertility Alinit did not influence the yield to any marked degree. An experiment conducted with maize for forage showed no difference in growth of plants in favor of Alinit.

Production of new types of forage plants—clovers and grasses, A. N. MCALPINE (*Trans. Highland and Agr. Soc. Scotland*, 5. ser., 10 (1898), pp. 135-165).—This article is a discussion of the work being done by John Garton in the line of producing new types of forage plants, especially clovers and grasses. The methods pursued are outlined in detail and the operations of artificially crossing beans, peas, clovers, and grasses are described. The experiments are not completed, but the following are some of the results obtained thus far: *Trifolium medium* was not fertile with pollen from *T. pratense*, and *T. pratense* produced no seed when pollinated with *T. medium*; no seed whatever was produced by crossing *T. pratense* with *T. hybridum* and *vice versa*; and the results remained the same when *T. repens* was substituted for *T. pratense*; red-flowered early and late varieties of crimson clover and white-flowered late varieties when crossed with each other produced a red-flowered progeny; a wild variety of *T. pratense* and commercial red clover were found to cross readily, and it is desired to originate a variety combining the well-developed stooling habit of the wild variety and the seed productiveness of the commercial red clover.

Eighteen species of clover, grown for experiment, and 17 varieties of grasses, obtained by crossing, are briefly described.

Systematic plant introduction, D. G. FAIRCHILD (*U. S. Dept. Agr., Division of Forestry Bul.* 21, pp. 24).—The purposes and methods of plant introduction are described at some length, and the desirability of the establishment of new plant industries, the securing of new varieties of plants already in cultivation, and the collection of species for breeding purposes pointed out. Suggestions are given for

the collection of plants and the necessity for the inspection of all collections in order that noxious weeds, injurious insects, and fungus parasites may not be introduced is stated.

Annual report of the botanist of the Nebraska State Board of Agriculture, C. E. BESSEY (*Nebraska State Bd. Agr. Rpt. 1897, pp. 107-140*).—Notes are given on the collection of grass exhibited at the State Fair in 1897, in which 21 collections, numbering 1,501 specimens, were shown. Notes are given on the botanical regions and districts of Nebraska and the forage problems of the different parts of the State are discussed.

Gram, chick-pea, or Idaho pea, J. G. SMITH (*U. S. Dept. Agr., Division of Agrostology Circ. 7, pp. 4, fig. 1*).—A description of this plant (*Cicer arietinum*), together with notes on its uses and cultivation. Although recently reported as a new forage plant native to the Rocky Mountains, this plant has been known for centuries in the Orient. Its value as a soil renovator and for feeding purposes is shown. It is stated that the leaves possess deleterious qualities, and the forage is said to be poisonous to horses on account of the excess of oxalic acid. Cattle are also injured to some extent, although less than horses. The plant, however, is not ordinarily grown as a forage crop, but for the seeds alone.

Thirty poisonous plants of the United States, V. K. CHESNUT (*U. S. Dept. Agr., Farmers' Bul. 86, pp. 32, figs. 24*).—This is a popular edition of Bulletin No. 20 of the Division of Botany (E. S. R., 10, p. 516). In the present publication several of the less poisonous plants have been stricken out and a small amount of new matter added. The plants described are fly amanits, death cup, American false hellebore, pokeweed, corn cockle, dwarf larkspur, Wyoming larkspur, purple larkspur, black cherry, woolly loco weed, stemless loco weed, rattlebox, caper spurge, snow on the mountain, poison ivy, poison oak, poison sumac, red buckeye, water hemlock, Oregon water hemlock, poison hemlock, broad-leaf laurel, narrow-leaf laurel, great laurel, staggerbush, branch ivy, jimson weed, black nightshade, bittersweet, and sneezeweed.

Some native fodder plants, J. H. MAIDEN (*Agr. Gaz. New South Wales, 10 (1899), No. 1, p. 37*).—*Tribulus hystrix*, *Swainsona campylantha*, *Aeschynomene indica*, *Rutidosia helichrysoides*, *Codonocarpus australis*, and *Croton verreauxii* are all mentioned as being valuable for forage in various parts of Australia.

An unusual phyto-bezoar, W. TRELEASE (*Pharm. Rev., 16 (1898), No. 2, pp. 66-70, pl. 1*).—Two balls composed of trichomes from cacti are described. They were taken from the stomach of a bull and were $3\frac{1}{2}$ and 4 in. in diameter, 16 of them having been found in the animal.

A contribution to the physiology of roots, A. RIMBACH (*Ber. Deut. Bot. Gesell., 17 (1899), No. 1, pp. 18-35, pl. 1*).—Studies are reported on the function of roots, the author classifying them as nourishing, adventitious, supporting, and storage roots.

On the decomposition of protein during germination, PRIANISCHNIKOW (*Bot. Centbl., 77 (1899), No. 3-4, p. 107*).—In a brief abstract the author states that experiments with a number of legumes in which the rapidity of the decomposition of protein was measured showed that the curves of decomposition and respiration are quite similar, although the first runs higher, the carbon dioxide falling off. The accumulation of asparagin is said to also trace a similar curve, but it ultimately goes higher than the decomposition curve.

On the reformation of proteids from the products of metabolism, PRIANISCHNIKOW (*Bot. Centbl., 77 (1899), No. 3-4, p. 108*).—Some 2 or 3 weeks after the splitting up of the protein in germinating seeds the formation of the protein is resumed, the asparagin and other amido compounds being utilized.

The influence of light upon the synthetic processes in green plants, W. PAL-LADIN (*Bot. Centbl., 77 (1899), No. 2, pp. 60, 61*).—Etiolated seedlings of *Vicia faba*, which were small and yellow and contained little protein and no carbon dioxide or starch, were grown in solutions containing 10 per cent of cane sugar, which was utilized as starch. It was possible to observe the effect of light upon such plants. The intensity of respiration was more than twice as great in the light as in the dark-

ness, and crude protein was formed in about the same proportion. There appeared to be a direct relation between the intensity of respiration and the production of crude protein.

Influence of light on the aldehyde content of green leaves, J. REINKE and E. BRAUNMÜLLER (*Ber. Deut. Bot. Gesell.*, 17 (1899), No. 1, pp. 7-13).—The aldehyde, which exists as condensation products in leaves, was found to be more abundant when the specimens had been kept for some time in the light.

Soil evaporation and plant transpiration, W. MAXWELL (*Landw. Vers. Stat.*, 51 (1898), No. 2-3, pp. 205-220).—This article has already appeared in the *Journal of the American Chemical Society* (E. S. R., 10, p. 721).

The influence of rain upon sugar cane, H. BRÜNING (*Tropenpflanzer*, 2 (1898), No. 12, pp. 363-365, figs. 2).

On the function of hydrocyanic acid in plants, M. SOAVE (*Ann. Farm.*, 1898, p. 481).—Experiments with sweet and bitter almonds.

On the utilization by the plant of the phosphoric acid in the soil water, T. SCHLOESING (*Jour. Soc. Agr. Brabant-Hainaut*, 1898, No. 50).

The significance of silicic acid in plants and its relation to lodging of cereals, V. VON SWIECICKI (*Die Bedeutung der Kieselsäure als Bestandtheil der Pflanzen und ihre Beziehungen zum Lagern des Getreides.* Halle, 1898, pp. 45).

The poisonous effects exerted on living plants by phenols, R. H. TRUE and C. G. HUNKEL (*Bot. Centbl.*, 76 (1898), No. 9, pp. 289-295; 10, pp. 321-327; 11, pp. 361-368; 12, pp. 391-398).

Biological studies on Alinit, J. STOKLASA (*Centbl. Bakt. u. Par.*, 2. Abt., 4 (1898), No. 12, pp. 507-513; 13, pp. 535-540).

The morphology and biology of the denitrification bacteria, H. JENSEN (*Centbl. Bakt. u. Par.*, 2. Abt., 4 (1898), No. 10, pp. 401-411; 11, pp. 449-460, figs. 8).

Symbiotic saprophytism, D. T. MACDONALD (*Ann. Bot.*, 13 (1899), No. 49, pp. 1-47, pls. 2, fig. 1).—This work was intended to extend the knowledge of the occurrence of mycorrhiza, the physiological relation between the two symbionts, the influence of mycorrhizal arrangement upon the development of the higher plant, and the experimental formation and variation of such structures. Ten species of hemisaprophytes, 1 holosaprophyte, and 4 autophytes were studied.

On the relation which exists between the evolution of certain organs in the fungi and in phanerogams, BOUDIER (*Compt. Rend. Congress Soc. Savantes*, 1898, pp. 149-167).

The effect of ethereal oils on fungi, T. BOKORNY (*Arch. Physiol.* [Pflüger], 73 (1898), p. 555).

Contributions to the biology of *Penicillium glaucum*, F. GUÉGUEN (*Bul. Soc. Mycol. France*, 15 (1899), No. 1, pp. 15-36, pl. 1).—Notes are given on the effect of various fungicides on *Penicillium glaucum* and cytological studies on the same.

On the presence of a soluble proteo-hydrolytic ferment in mushrooms, E. BOURQUELOT and H. HÉRISSEY (*Bul. Soc. Mycol. France*, 15 (1899), No. 1, pp. 60-67).—Notes the presence in a number of mushrooms, as well as in *Aspergillus niger*, of a ferment capable of digesting casein.

On the presence of emulsin in lichens and fungi, H. HÉRISSEY (*Bul. Soc. Mycol. France*, 15 (1899), No. 1, pp. 44-48).—Notes the presence of emulsin in a number of lichens and fungi in which it had not been previously observed.

The scientific preservation of mushrooms and the localization of the toxic principle in them, E. PROTHIÈRE (*Compt. Rend. Congress Soc. Savantes*, 1898, pp. 212-217).

Methods in planktology, G. W. FIELD (*Rhode Island Sta. Rpt.* 1897, pp. 120-149, pls. 3).—The author describes the different methods adopted for collecting the organisms from water and points out some of the sources of error in different machines. A bibliography on the subject is also given.

The Point Judith pond, G. W. FIELD (*Rhode Island Sta. Rpt.* 1897, pp. 117-119,

pls. 2).—A description is given of the biological laboratory situated at Point Judith pond, and a brief review of the investigations which have been carried on at that point.

METEOROLOGY—CLIMATOLOGY.

Meteorological report, N. HELME (*Rhode Island Sta. Rpt. 1897*, pp. 618-633).—This includes general notes on the weather during 1897 and a tabulated record of observations on temperature, precipitation, cloudiness, and prevailing winds during each month of 1897, with a summary for the years 1890-1897, inclusive. The summary for 1897 is as follows:

Temperature (degrees F.).—Maximum, 90, September 10; minimum, 1, January 20; mean, 48.3; annual range, 89; highest monthly mean, 70.6, July; lowest monthly mean, 28.2, February; highest daily mean, 76, September 10; lowest daily mean, 6, January 19. *Precipitation* (inches).—Total (rain and melted snow), 51.25; greatest monthly, 10.25, November; least monthly, 0.89, October; greatest in 21 consecutive hours, 5.17, November 2; snow fall—total, 48; greatest monthly, 19.5, January; least monthly, 3, March. *Weather*.—Number of clear days, 129; number of fair days, 126; number of cloudy days, 110; number of days on which there was precipitation of 0.01 in. or more, 128. *Prevailing wind*, southwest.

The meteorology of 1897 (*Trans. Highland and Agr. Soc. Scotland, 5, ser., 10 (1898)*, pp. 401-408).—"A table gives a comparison of the winds, mean pressure, temperature, rainfall, cloud, and sunshine of 1897 as compared with the previous 41 years' averages," and the weather conditions during each month are discussed in detail with brief notes on the character of the principal crops of the year.

Results of meteorological observations made in the depressed area of the center of the continent of Asia (Luktshoun), A. DE TILLO (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 3, pp. 154-156*).

The temperature and moisture of the air in open fields and pine and beech woods, J. SCHUBERT (*Ztschr. Forst. u. Jagdw., 31 (1899), No. 2, pp. 91-99*).

Observations on the sun at the observatory of Lyons during 1898, J. GUILLAUME (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 3, pp. 158-160*).

Climate of the Klondike, J. HANN (*Met. Ztschr., Jan., 1899; abs. in Nature, 59 (1899), No. 1532, p. 448*).—A compilation of available data.

WATER—SOILS.

Lysimeter experiments, J. HANAMANN (*Ztschr. Landw. Versuchsw. Oesterr., 1 (1898), p. 399; abs. in Chem. Ztg., 22 (1898), No. 99, Repert., p. 313*).—The author reports the results of a series of investigations with lysimeters which show that drainage water removes more plant food from bare soils than from those covered with crops, the most important loss being that of nitrogen, and this was especially great in the warmer portion of the year, when nitrification is most active. The loss was smallest in those soils bearing plants which made the greatest demand upon the soil and covered the soil most completely throughout the year. In fallow soils there was a very large loss of nitric nitrogen. The largest amounts of nitrates were taken up from the soil by corn, barley, sugar beets, and horse beans, plants whose nitrogen require-

ments are very great. The loss of nitrogen was smallest in alluvial soils producing a luxuriant growth of plants.

The greatest loss of lime was observed in the bare alluvial soil. Even in soils bearing crops the loss of lime was considerable, especially where potash manures were used. It is estimated that in soils rich in lime the annual loss of this constituent may be as much as 2,676 to 3,568 lbs. per acre.

Only very small quantities of phosphoric acid were found in the drainage water of the different soils. Potash was removed in somewhat larger amounts. The loss of this constituent was greatest in bare soils, and least in soils bearing plants with extensive root systems. The loss of sulphuric acid was but slightly smaller in the soil bearing crops than in bare soils. The loss of chlorine, however, was six times as great in the bare soils as in those bearing crops. Soils bearing luxuriant vegetation yielded only a small amount of drainage water, even with abundant rainfall. For this reason the losses were reduced to a minimum in such soils. The perennial plants are best adapted to preventing loss by drainage.

Composition of drainage water from fertilized and unfertilized moor soils, with special reference to nitrogen, B. TACKE, H. IMMENDORFF, and H. MINNSEN (*Landw. Jahrb.*, 27 (1898), *Sup.* 4, pp. 319-391, *fig. 1*).—These studies were made with soils in glass cylinders 25 by 35 cm. in size, fitted with a device for drawing off the percolating water at will. The results obtained indicate that a very small part of the nitrogen compounds of upland moor soils is readily transformed into ammonia and nitrates. The rest firmly withstands such change. In lowland moor soils the amount of such readily transformed compounds is much greater. A moderate application of lime which does not completely neutralize the acids present does not increase the transformation of the insoluble nitrogen compounds, but promotes nitrification of the more readily decomposable compounds by improving the texture and aeration of the soil. The application of larger amounts of lime resulted in increased nitrification in the upland moor soils, but had little influence on lowland moor soils rich in lime. In sand-covered lowland moor soils the conditions were more favorable for nitrification than in unlimed or normally limed and fertilized upland moor soils. Applications of potash salts, phosphates, and lime in normal amounts did not materially increase the ammonia in the drainage water of upland moor soils. Kainit and Thomas slag decreased the amount of ammonia in the drainage water of lowland moor soils. When nitrate of soda was added to the other fertilizers, however, the amount of ammonia in the drainage was appreciably increased.

The phosphorus compounds of moor soils are very insoluble, and those applied in fertilizers are quite firmly fixed in the soil. With continued applications of phosphoric acid, however, more of this substance appears in the drainage.

The natural potash, magnesia, and lime of moor soils are to some extent soluble in water, but the larger part is insoluble. A considerable amount of the potash applied in fertilizers to upland moor soil passes into the drainage. The rest is quite firmly fixed in the soil. The natural potash of lowland moor soils is somewhat more insoluble than that of the upland moors. The absorptive power of the latter for potash, however, is practically the same as that of the former. Only after repeated applications of lime was the solubility of the soil potash increased. Applications of potash increased the solubility of the soil lime to a marked degree. Increased amounts of lime were not found in the drainage water following the application of lime.

Investigations on the phosphorus compounds of moor soils, B. TACKE (*Landw. Jahrb.*, 27 (1898), *Sup. 4*, pp. 303-348).—Twelve samples of moor soil (burnt and not burnt) were treated in a variety of ways with a number of different solvents (hydrochloric, nitric, acetic, oxalic, and citric acids, carbonic acid water, ammonium oxalate and carbonate, and water). Boiling for 8 hours with 5 per cent hydrochloric acid dissolved all the phosphorus compounds present. The larger part of the phosphorus compounds was also dissolved by 10 per cent ammonia solution, especially when the soils had been previously treated with 0.5 per cent hydrochloric acid. The phosphorus compounds dissolved from the soil by acids were found to be diffusible. Drying and heating increased the solubility of the phosphorus compounds of the soils in the above reagents.

Pot experiments with some of the soils used in the above investigations showed that the phosphoric acids of soils which had been dried or burnt was much more available to plants than that of soils not so treated.

The changes which moor soils undergo under culture and manuring, G. SCHLIEBS and H. MINSEN (*Landw. Jahrb.*, 27 (1898), *Sup. 4*, pp. 525-547).—The principal change noted was an increase of potash and phosphoric acid (especially the latter) in the surface soil. There was no increase of nitrogen where nitrate of soda was used, although an increase was observed where less soluble forms of nitrogen were applied. In general, the increase in the soil supply of a given constituent under fertilization was greater the less abundant the applications of the other constituents. The increase in soil supply of potash and phosphoric acid did not as a rule result in such an increased yield as to render moderate applications of these constituents unnecessary. This is explained by the insolubility of the potash and phosphoric acid absorbed by the soil (see above). The continued use of potash salts resulted in a decrease in the lime of the surface soil, but this was partly or completely corrected by the lime in phosphatic substances, such as Thomas slag, which had been used.

Continued application of fertilizers resulted in an increase of potash and phosphoric acid as well as lime in the lower layers of the soil.

The potash, being more soluble, accumulated more rapidly here than phosphoric acid. The movement and accumulation of the different constituents in the soil are determined largely of course by the texture and tilth of the soil, the amount of rainfall, etc.

On the analysis of soil as a guide to its fertility, B. DYER (*Trans. Highland and Agr. Soc. Scotland*, 5. ser., 10 (1898), pp. 26-52).—This is essentially “a popular summary of the more extensive paper” by the author, entitled “On the analytical determination of probably available mineral plant-food in soils” published in 1894 (*E. S. R.*, 5, p. 1013). Some reference, however, is made to hitherto unpublished results obtained in a study of samples “representing not only the first 9 in. of soil, but also 2 succeeding depths of 9 in. each” from wheat plats at Rothamsted.

“[These results show] that if we regard only the total phosphoric acid, the ratio between that found in the soils phosphatically starved and that in those phosphatically manured (with superphosphate or with farmyard manure) is about 1:1.7, a difference which is sufficiently striking when the soils are all known to be from one field, but from which, as a mere analytical result, one could not draw very strong conclusions if the soils happened to be from different neighborhoods. When, however, we regard the ‘available’ (*i. e.*, citric-acid-soluble) phosphoric acid in the same way, we find a ratio of about 1:6. It is interesting to notice that the ratios, both for total phosphoric acid and for citric-acid-soluble phosphoric acid, are practically the same as those found in the examination of the Heos field barley soils already discussed.”

A comparison was also made of the potash content of wheat plats to which no potash had been applied for 40 or 50 years and that of plats to which potash had been applied.

“In the case of the hydrochloric-acid-soluble potash, the ratio between the 2 sets of soils is 1:1.1; but when we regard the ‘available’ potash, we find, as in the case of the barley soils, an overwhelming ratio of 1:8. . . .

“A knowledge of the proportion of potash soluble in hydrochloric acid is in most cases of very small value. I venture to think, however, that the determination of the potash dissolved by a dilute solution of citric acid is possessed of much more value.”

The analyses of Jamaica soils, F. WATTS (*Jour. Jamaica Agr. Soc.*, 3 (1899), No. 1, pp. 17-22).—Mechanical and chemical analyses of 6 samples of soil from different parts of the island are reported. “These represent 3 very distinct types of soil—the red soils from Mocho in Clarendon and Brokenhurst in Manchester, the sandy soil from the St. Andrew’s Plain at Barbican, and the heavier low-lying soils of Hartlands in St. Catharine.” The red soils consist largely of fine silt or clay (45-61 per cent). They contain a very small amount of insoluble matter (about 19 per cent), due to an abnormal amount of soluble oxid of iron and alumina (46 per cent) and combined water. “Although lying upon the limestone, and doubtless derived from it, these soils are singularly deficient in carbonate of lime; if all the carbonic acid be calculated into terms of carbonate of lime we have only 0.58 per cent in the Mocho soil and 1.57 per cent in the case of the Brokenhurst sample.” The proportion of potash in these soils is not large (0.05 to

0.15 per cent). Phosphoric acid is abundant (0.35 to 0.91 per cent) but very insoluble in 1 per cent citric acid. The proportion of humus and nitrogen is fairly large.

The Barbican soils contain a large amount of sand (44 per cent) and a small quantity of fine silt and clay (19 per cent). "The chemical analysis shows that there is a plentiful supply of potash [0.22 per cent] and of phosphoric acid [0.26 per cent] soluble in hydrochloric acid, and also that a fair proportion of each of these constituents is soluble in citric acid [0.16 and 0.22 per cent]. On the other hand, there is a striking deficiency of lime as carbonate [0.03 per cent], of humus [1.45 per cent], and of nitrogen [0.08 per cent]." A considerable portion of the lime is believed to be in the form of silicate.

The Hartlands soils contain a fair amount of sand (39 to 45 per cent), the larger part of which is quite fine. The proportion of fine silt and clay is not excessive (29 to 40 per cent). "These soils are fairly rich in potash which is soluble in moderate quantity. . . . The amount of phosphoric acid is not large and the quantity soluble in citric acid is small. . . . The proportion of carbonate of lime is small."

Influence of atmospheric agents on soil bacteria, M. CRENDIROPOULOS (*Rev. Hyg.*, 20 (1898), No. 8, pp. 697-705).

Purpose, value, and method of field experiments on moor soils, B. TACKE (*Landw. Jahrb.*, 27 (1898), Sup. 4, pp. 414-430, fig. 1).—A general discussion (with plans) of this subject based upon experience at the Moor Experiment Station at Bremen.

On the presence of ferrous carbonate in the iron deposits of moors, H. SCHÜTTE (*Landw. Jahrb.*, 27 (1898), Sup. 4, pp. 548-557).—Chemical examinations showing the presence of this substance in a number of samples of bog-iron deposits are reported.

Cultivation of soil, P. P. DEMÉRAIN (*Compt. Rend. Acad. Sci. Paris*, 128 (1899), No. 8, pp. 474-479).—This is a summary of investigations on the influence of different methods of cultivation, on the water supply, and nitrification in the soil, which has been noted elsewhere (E. S. R., 10, p. 727).

FERTILIZERS.

The use and value of seaweed as manure, J. HENDRICK (*Trans. Highland and Agr. Soc., Scotland*, 5. ser., 10 (1898), pp. 118-134).—This is a popular article, based principally upon investigations and observations by the author.¹

Analyses of cut weed or black wrack (*Fucus nodosus* and *F. vesiculosus*), driftweed, principally *Laminaria*, and dulse (*Rhodymenia palmata*) are reported and their fertilizing value as compared with barnyard manure is discussed.

Comparative field tests of seaweed, barnyard manure, and other fertilizers on potatoes were carried out under the supervision of the author in 1895 and 1896 in 3 different localities.

"[From the result of these experiments] it will be seen that, weight for weight of manure, seaweed gives just as great a crop of potatoes as farmyard manure. When superphosphate is applied along with the seaweed the crop is in every case

¹ See also *Agr. Students' Gaz.*, n. ser., 9 (1898), No. 2, pp. 41-49 (E. S. R., 10, p. 833).

increased, and except in [one instance], where analysis shows the soil itself to have been high in "available" phosphate, the increases are very considerable . . . Seaweed with super-phosphate gave a larger crop in every case than farmyard manure with superphosphate [or potash] or with farmyard manure alone . . .

"On the other hand, dung had the advantage over seaweed in quality of produce. . . . There was no doubt that the seaweed potatoes were less mature than the dung ones. They were softer and less mealy when boiled; and in every case it was held that the results of the seaweed plats would have been improved if they could have been allowed to grow for a fortnight longer. It is therefore probable that seaweed would give even better results with late potatoes.

"As no nitrogenous manure was applied with the seaweed in any of the experiments and as [one of] the soils was very deficient in nitrogen, the results would seem to indicate that the nitrogen of seaweed readily becomes available to potatoes, and is, on the whole, of equal value to that of dung.

"The field experiments, then, confirm the results of analysis, and show that seaweed is, weight for weight, as good a manure for potatoes as dung, but that to get the best results with it it should be supplemented with phosphate. . . .

"So far as these experiments go, then, there does not seem to be much ground for the general belief that muriate of potash is not a suitable manure for potatoes."

The starfish in Narragansett Bay, G. W. FIELD (*Rhode Island Sta. Rpt. 1897, pp. 150-165, pls. 8*).—In connection with a study of the life history and habits of the starfish (*Asterias forbesii*), an enemy of the oyster, analyses with reference to fertilizing constituents were made, with the following results:

Composition of starfish.

	Calculated to live unrinsed fishes as received.	Calculated to absolutely dry starfishes rinsed with fresh water before drying.
	<i>Per cent.</i>	<i>Per cent.</i>
Loss by rinsing with fresh water and complete drying	65.43
Crude ash	20.34	58.84
Lime (calcium oxid)	9.62	27.82
Potash (potassium oxid)23	.66

Solubility of the phosphoric acid of Thomas slag and crude phosphates in upland moor soils as determined by the amount of free humus acids present, B. TACKE and H. MINSSEN (*Landw. Jahrb., 27 (1898), Sup. 4, pp. 392-413*).—In these experiments, in which a variety of phosphates—including among others Florida and Carolina phosphates and Thomas slag—were tested in pots, it was found that the solubility of the phosphates depended upon the amount of free humus acids present. Neutralizing the soil with basic substances, such as lime, destroyed the solubility of the crude phosphates, although a part of the phosphoric acid of Thomas slag was still soluble under these conditions. The citrate-insoluble phosphoric acid of the slag, however, was not dissolved to any greater extent in the soil than that of the crude phosphates.

Utilization by plants of the phosphoric acid dissolved in soil water, T. SCHLOESING (*Compt. Rend. Acad. Sci. Paris*, 127 (1898), No. 21, pp. 820-822; *abs. in Rev. Sci. [Paris]*, 1. ser., 10 (1898), No. 23, p. 725).—Sterile sandy soils especially deficient in phosphoric acid were watered with nutritive solutions containing varying amounts of phosphoric acid and planted to various crops. On the soils receiving no phosphoric acid the plants made little or no growth. On those receiving phosphoric acid in proportions similar to those found in ordinary soils the plants grew well. With solutions containing 2 mg. of phosphoric acid per liter excellent crops of maize were obtained, and with solutions containing from 0.5 to 1 mg. of this substance per liter the yield of wheat was from 13.35 to 24.03 bu. per acre.

Trial of phosphates, C. O. FLAGG and J. A. TILLINGHAST (*Rhode Island Sta. Rpt. 1897*, pp. 391-408, pls. 2, *diagms. 1*).—The plan of these experiments and the results heretofore obtained have been previously published (*E. S. R.*, 9, p. 938). A hay crop was grown in connection with these experiments, and the yields in 1896 and 1897 are reported in tables and the results described. The different materials used to supply phosphoric acid were dissolved boneblack, dissolved bone, dissolved phosphate rock, fine ground bone, slag meal, floats, raw aluminum phosphate, ignited aluminum phosphate, and double superphosphate. These substances were applied on two series of plats, one of which was unlimed, while the other had received an application of 1 ton of air-slaked lime per acre in 1894.

“The 3 insoluble phosphates, fine ground bone, slag meal, and floats, thus far maintain the lead in pounds of hay produced, slag meal holding the first place in the unlimed series. The aluminum phosphates thus far appear to be quite inferior forms of phosphoric acid when used upon an acid soil without an application of lime; and when in the raw form, even in connection with lime, produced a smaller crop than the plat which received no phosphoric acid. The ignited form, used in connection with lime, produced, in 1897, the second largest yield, but occupies sixth place in the total production for 2 years. The last one-third ration has yet to be applied as an annual top-dressing to the plats receiving the soluble phosphates before all will be on the same basis, but the lead now held by 3 forms of insoluble phosphate will doubtless give them the advantage even then.”

In the 2 seasons the lime plats yielded 6,634.42 lbs. of hay per acre more than the unlimed plats. “If . . . we charge the entire cost of the lime at \$8 per ton to these 2 hay crops and calculate the value of the increase in the hay crop at \$14 per ton, we have a profit of \$38.44 per acre due to the use of lime in connection with fertilizers on an acid soil.” Redtop (*Agrostis vulgaris*) formed the bulk of the hay crop on the unlimed plats and timothy (*Phleum pratense*) on the limed plats. The use of air-slaked lime favored the growth of the timothy. “When soils are acid, timothy quickly disappears from the grass field and redtop or dent or, perhaps, sorrel takes its place.”

Tests of nitrogenous fertilizers on hoed plants, C. DUSSERRE (*Chron. Agr. Vaud*, 11 (1898), No. 23, pp. 668-672).—An account is given of 2 experiments with varying amounts (200 to 500 kg. per hectare) of

nitrate of soda on fodder beets, (1) on alluvial soil recently drained, very rich in organic matter and nitrogen, and with a humus subsoil also rich in nitrogen, and (2) a dry gravelly soil, poor in nitrogen. Analyses (food constituents) of the beets grown are reported.

There was a profitable return in both cases from the use of nitrate, even with the larger applications, but naturally the return was greatest in case of the gravelly soil poor in nitrogen.

The results show in general that the nitrate was effective only when used in connection with a sufficient supply of the mineral elements phosphoric acid, potash, and lime; and indicate that the exclusive and repeated use of nitrogenous fertilizers destroys the equilibrium in the soil and reduces the yield.

Observations regarding the relative assimilability of various forms of nitrogen upon an acid soil, limed and unlimed, H. J. WHEELER, B. L. HARTWELL, and G. E. ADAMS (*Rhode Island Sta. Rpt. 1897, pp. 211-253, pls. 2*).—This is a summary account of pot experiments begun in 1893 (E. S. R., 7, p. 378). The experiments have been made in pots 18 in. in diameter and 26 in. deep. Like quantities of dissolved boneblack, muriate of potash, and nitrogen in several forms (dried blood, tankage or ground leather, nitrate of soda, and sulphate of ammonia) have been added annually to each pot. Corn was grown in 1893, oats in 1894, rye in 1895, and barley in 1896 and 1897. The pots were divided into 2 series, one limed and the other unlimed. The data reported include yield of crop, percentage of nitrogen in dry matter, and total nitrogen removed by the crop. The results are summarized as follows:

“On a very acid (sour) soil sulphate of ammonia has worked like a poison instead of as an effective fertilizer.

“Where air-slaked lime was applied with sulphate of ammonia, the nitrogen proved nearly as valuable as like quantities in form of nitrate of soda.

“Dried blood, on the acid soil, yielded some nitrogen to the plants and proved its marked superiority to the leather.

“When used in connection with lime the nitrogen of the dried blood became nearly as effective as like amounts in the form of nitrate of soda, while nitrogen in the form of leather was very ineffective even when, by liming, the conditions for its nitrification were made as favorable as possible. That the conditions for nitrification were favorable in the limed pots is shown by the fact that the nitrogen of the sulphate of ammonia and dried blood became almost as effective as nitrate of soda.

“These results bring out plainly the fact that upon an acid soil, where nitrification progresses but slowly, much of the money invested in the best forms of organic nitrogen, such as blood, meat, and fish, is practically wasted, and since these forms make up the major part of the nitrogen of most of the commercial fertilizers sold in the State, the importance of testing soils for their acidity and supplying lime where needed can not be too strongly insisted upon.”

Observations in connection with a soil test continued for 8 successive years, H. J. WHEELER and J. A. TILLINGHAST (*Rhode Island Sta. Rpt. 1897, pp. 177-184*).—This is an account of a continuation of an experiment begun in 1890 (E. S. R., 9, p. 936), in which

nitrogen has been applied each year in the form of nitrate of soda, phosphoric acid in form of dissolved boneblack, and potash in form of muriate of potash, with and without the addition of lime. During the earlier years the crop experimented with was corn. Subsequently a large variety of other crops were used. In 1897 the plants grown were crimson clover, common white beans, sunflower, summer squash, and corn. The results are reported in detail and summarized as follows:

"The first year's experiment with maize indicated a probable need of potash. Experiments for 3 successive years with the same crop showed in a most decisive manner that phosphoric acid was more deficient in the soil than nitrogen or potash.

"Most of our agricultural plants gave indications that their individual requirements for phosphoric acid on our soil were determinable in a soil test as well by maize as by the use of each of them.

"Sunflowers, by virtue of greater requirements for potash or of less ability to extract it from the soil, are probably not well calculated for use in determining phosphoric acid deficiencies for most other plants. White beans, summer squashes, and crimson clover seem also less desirable for such a use than the cereals.

"Liming, an unusual amount of water, or possibly both factors, seem capable of rendering assimilable some of the otherwise inert phosphates already existing in the soil."

On the substitution of soda for and its value in connection with potash, H. J. WHEELER and J. A. TILLINGHAST (*Rhode Island Sta. Rpt. 1897, pp. 226-240, pls. 4*).—The experiments here reported were a continuation of those of previous years (E. S. R., 9, p. 933). The following is a summary of the results thus far obtained:

"It may be stated at this time that with each succeeding year soda, when used without potash, has steadily deteriorated in its action when compared with the results from plants manured with potash, but without soda.

"Where soda has been added in increasing quantities to a full potash ration, little or no benefit from its use has been apparent. On the other hand, the addition of increasing quantities of potash to a full soda ration, has, especially in the last 2 years, been attended with most marked gains.

"In the instances where potash and soda have both been employed in varying amounts, marked evidence of benefit from soda is noticeable in the results for 1897, particularly where the potash ration was reduced to one-fourth of the maximum amount.

"There seems to be some doubt if it would prove an economical practice to reduce the supply of potash sufficiently to gain the greatest benefit from the soda, for by so doing the total crop seems to be seriously reduced. It may be possible that certain plants may be able to make use of soda without the danger just mentioned. This point can only be determined by further experimentation.

"It is not known at present, and can not be until the analytical data are all available, whether the soda has probably acted as a direct plant food, or indirectly by virtue of its having liberated some potash or other manurial ingredients. It is hoped that something in this connection will be ready for publication in the near future."

A study of the needs of certain Rhode Island soils, H. J. WHEELER, C. O. FLAGG, and G. E. ADAMS (*Rhode Island Sta. Rpt. 1897, pp. 185-201, pls. 7*).—This is an account of cooperative experiments during 1897 in continuation of those of previous years (E. S. R.,

9, p. 937). The main results of these experiments are summarized as follows:

"In experiments with beets already conducted in 15 localities in the State marked benefit from liming has been observed in every case but one. The smallest gain has been 21 per cent, the next smallest 37 per cent, while in the other cases the crop has been practically doubled, or increased several times.

"Experiments with barley, in 1896, indicated a more or less general need of lime, but the results were far less marked than with beets.

"With but one or two exceptions the most striking benefit from liming has been noticeable, in 1897, in connection with both red clover and timothy (*Phleum pratense*) in various sections of the State. Liming increases the relative amount of timothy in mixtures of that grass with redtop, and also the total weight of the hay crop on many soils. Practically all of the reasonably heavy soils, and particularly such as are well supplied with humus, have been found to be less in need of nitrogen than of phosphoric acid."

Five years' observations upon the growth of plants upon an acid upland soil, limed and unlimed, H. J. WHEELER and J. A. TILLINGHAST (*Rhode Island Sta. Rpt. 1897, pp. 202-225, pls. 2*).—The experiments in 1897 were conducted on the same plan as that followed in previous years (E. S. R., 9, p. 935). The results obtained are as follows:

"Of all the grasses thus far tested, none seemed to stand so much in need of lime on acid soil as Kentucky blue grass and timothy.

"Orchard grass and meadow fescue, though less injured by soil acidity (sourness) than Kentucky blue grass or timothy, nevertheless show great benefit from liming. Sheep fescue is also benefited by liming to a considerable extent, though it gives no promise of value for hay in this section.

"Awnless brome grass, redtop, and Rhode Island bent, though valuable grasses, do not seem to be susceptible of great injury, even upon quite acid soils. This observation furnishes a satisfactory explanation of the fact that timothy and clover give way rapidly to redtop and Rhode Island bent on many of our New England farms.

"This season's trial indicates wonderful benefit from the use of lime in the growing of asparagus. These observations are to be continued if possible.

"New Zealand spinach, like the ordinary varieties, seems to be much helped by liming.

"Spinach and asparagus give much better results from nitrogen in form of nitrate of soda than from like quantities in form of sulphate of ammonia. Experiments are in progress for the purpose of ascertaining definitely, if possible, to what this difference is due.

"Strawberries, currants, and gooseberries have shown this season some benefit from liming, yet it will be necessary to wait a year or two before definite conclusions in the matter can be drawn.

"Judging from the growth only, raspberry plants appear to show some benefit from liming, while no noticeable differences in blackberry plants have been observable.

"Delaware grapevines seem to be injured in a marked degree by sour soil, and correspondingly helped by liming, while the Concord vines appear to be comparatively indifferent in this particular.

"Among the other tests made the past season the orange quince, Golden Sweet apple, American elm, and American linden show more probability of ultimate benefit from liming than the Crawford Early peach, Baldwin apple, Bartlett pear, sugar maple, or American white birch. In future years more conclusive data should be obtainable in relation to the small fruits, orchard and forest trees."

On the action of burnt lime and marl on sandy soils, B. TACKE, H. IMMENDORFF, A. SALFELD, and F. WOLFF (*Landw. Jahrb.*, 27 (1898), *Sup. 1*, pp. 131-150).—Experiments in the laboratory, greenhouse, and field tend to show that fall applications of burnt lime may injuriously affect the growth of leguminous plants by the impoverishment of the soil in assimilable nitrogen. The lime, however, did not appear to affect injuriously the root tubercle organisms applied in soil, although on uninoculated soils the plants grew much better where marl was applied than where burnt lime was used. This is believed to be due to the fact that the marl contained the root tubercle organisms in considerable amount.

Field experiments on upland moor soils and moor meadows by the Moor Experiment Station at Bremen during 1892-1897, B. TACKE, F. GAAZ, and H. MENKHAUS (*Landw. Jahrb.*, 27 (1898), *Sup. 1*, pp. 1-258, pls. 1).—These include experiments with different crops and with different combinations of fertilizers, the use of sand on upland moors, comparison of barnyard manure and commercial fertilizers on untreated upland moors, drainage to different depths, and applications of calcareous manures.

In experiments with different forms and amounts of phosphoric acid, potash, and nitrogen on moor soils the best results were obtained on the average from applications of 100 kg. per hectare of potash, 100 to 125 kg. of phosphoric acid, and 75 kg. of nitrogen.

In comparative tests of Thomas slag, precipitated phosphate, and Algerian phosphate on upland moors, the Algerian phosphate gave a more profitable return than Thomas slag, especially when applied in somewhat larger amounts (one-fourth more) than the latter on moor soils recently brought under cultivation.

In comparative tests of kainit, carnallit, and 38 per cent "manure salt" on upland moor soils the use of concentrated manure salt was found profitable, especially on potatoes, even when applied at the rate of 200 kg. per hectare in the spring, but carnallit and kainit applied in the same way reduced both the yield and starch content of potatoes. The reduction in starch content appeared to be due not to a lowering of the percentage of starch in the dry matter, but, as a rule, to an increase of water in the tuber. The injurious effect of the potash salts appeared to be lessened by the application of basic substances, such as lime, Thomas slag, etc.

Experiments with varieties of potatoes, oats, and rye are reported, but the results are either inconclusive or mainly of local interest.

A series of experiments were made on upland moors, the surface layers of which were mixed with a layer of sand 10 to 15 cm. thick. A variety of crops were grown on the soil and they were invariably benefited by the addition of the sand. In the case of cereals the increase in the yield of straw was greater than that of grain.

Comparative tests of barnyard manure and commercial fertilizers on untreated upland moors gave inconclusive results.

The results of comparative tests of drainage of upland moors to depths of 50 to 150 cm. indicate that for potatoes and rye, which are the principal moor crops, a depth of 50 cm. gives the best results, especially for new soils. As culture continues the depth of drainage may be increased without injury.

Burnt lime, marl, chalk, and gypsum in varying amounts were compared on a number of different crops and upland moor soils. The results indicate that as a rule these manures increased the productivity of the soil principally by improving the porosity and drainage of the soil and thus increasing the depth to which the roots of plants could descend.

In experiments on the action of different forms and amounts of potash and phosphoric acid on upland and lowland moor meadows it was found that combinations of kainit and Thomas slag gave an increased yield when other conditions of growth were favorable. Crude phosphates were found to be very effective when considerable amounts of acid were present in the soil. The character of the grasses was much improved by the use of fertilizers. An improvement was also noted in the composition of the individual grasses grown on the fertilized soil. This was shown in an increase in the percentage of protein. The grasses grown with fertilizers contained a higher percentage of water than those grown without fertilizers. The dry matter of the hay grown on fertilized soils contained higher percentages of potash and phosphoric acid than the averages given by Wolff. Hay from the lowland moors contained 2.17 per cent of potash and 0.57 per cent of phosphoric acid, while that from the upland moors contained 1.95 per cent of potash and 0.79 per cent of phosphoric acid.

Pot experiments on moor soils at the Moor Experiment Station at Bremen, B. TACKE and H. IMMENDORFF (*Landw. Jahrb.*, 27 (1898), *Sup. 4*, pp. 259-300, pls. 19, fig. 1).—Accounts are here given of pot experiments with upland and lowland moor soils, including tests of nitrogenous and phosphatic manures on lowland moor soils, studies on the optimum water content of upland and lowland moor soils, and on the action of underground liming and of naturally occurring compounds of phosphoric acid and iron on upland moor soils.

The experiments with nitrogenous fertilizers on lowland moor soils showed that even in cases in which the soil contained from 2.52 to 3.39 per cent of nitrogen the yields of oats, rye, and sugar beets were greatly increased by applications of nitrogen. The more favorable the conditions for nitrification and the more rapid this process took place in the soil the less the benefit from nitrogenous fertilizers.

In experiments on the action of phosphoric acid on lowland moor soils containing varying amounts of phosphoric acid, applications of phosphoric acid ceased to increase the yield of oats when the soil contained 0.44 per cent of phosphoric acid, and were without effect on the yield of wheat when the amount present in the soil was 1.23 per cent.

Only on soils very poor in phosphoric acid did water-soluble phosphoric acid produce better effects than Thomas slag containing a high percentage of citrate-soluble phosphoric acid. The after effect of the latter was also as a rule greater. Examinations of the soils used in these experiments indicated that the total phosphoric acid was not always a safe index of their phosphoric acid requirements, but this was dependent largely upon the form in which the phosphoric acid was present in the soil. Soils which contained phosphoric acid in form of vivianite, or in the transition stages between vivianite and ferric phosphate, stood less in need of phosphoric acid fertilizing than those which contained ferric phosphate.

In experiments on the optimum water content of lowland moor soils it was found that with leafy plants, like oil radish, the largest yield was obtained with the highest amount of water (75 per cent of the water capacity of the soil). With oats the maximum yield was obtained with a water content of 65 per cent. In similar experiments on upland moor soils the highest yields of both crops were obtained with saturated soil (84.7 per cent of water).

Red earth containing 2.08 per cent and vivianite containing 14.51 per cent of phosphoric acid, 2 substances which naturally occur in moors, were tested in comparison with Thomas slag. The results show that these substances have considerable value as fertilizers.

Fertilizers, E. B. VOORHEES (*New York: The Macmillan Co., 1898. pp. XIV+335*).—When we consider the relation of the experiment stations in this country to the fertilizer question it seems peculiarly fitting that the preparation of this volume of the Rural Science Series should have been intrusted to the director of an agricultural experiment station, and especially of a station like that of New Jersey, which has done so much to promote the intelligent use of fertilizers.

As the subtitle states, the book treats of the source, character, and composition of natural, home-made, and manufactured fertilizers, with suggestions as to their use for different crops and conditions. The following is a summary of the topics treated: The natural fertility of the soil and sources of loss of the elements of fertility; the functions of manures and fertilizers and the needs of artificial fertilizers; the sources and nature of the various commercial forms of nitrogen, phosphoric acid, and potash, as well as of miscellaneous fertilizing materials, including, among others, green manures and soil amendments; the analysis and purchase of fertilizers; methods of using fertilizers; and fertilizers for special crops—cereals and grasses, potatoes, sweet potatoes, tomatoes, sugar beets, green forage plants, market garden crops, orchard fruits and berries, cotton, tobacco, sugar cane, etc.

The work is intended for "the general reader as well as the student," and aims "to point out the underlying principles and to discuss in the light of our present knowledge of the subject some of the important problems connected with the use of fertilizers."

In order that each farmer may intelligently apply the results of scientific investigation to his own conditions the author outlines a plan of farm experiments. Great emphasis is laid on the importance of the systematic use of manures and fertilizers, a chapter being devoted to a discussion of systems of fertilization adapted to various systems of rotation and farm management, conditions of soil, etc.

FIELD CROPS.

A report of progress of investigations in the chemistry of wheat, G. L. TELLER (*Arkansas Bul.* 52, pp. 53-81).—This is a continuation of the author's investigation (*E. S. R.*, 8, p. 854). He refers to his contention that the wheat proteid designated by Osborne and Voorhees as a proteose is gliadin, and offers "further proof that the conclusion is correct."

Most of the bulletin is devoted to a study of the changes in wheat from the time the grain began to set until it was overripe. A half acre of wheat which gave promise of being very uniform was used for the investigations, but as the wheat matured the field was found to be less uniform than expected. Beginning May 22, when the wheat was past blooming and the grain was set, cuttings were made daily at the same hour on 42 successive days, about one-half of each cutting being dried on the straw, and the heads being cut from the other half and dried separately. The wheat from each cutting was thrashed and cleaned, "that used for analysis being hand picked to free it from all foreign matter." The number of kernels in 10 gm. of each sample was determined. This shows a quite regular decrease from 3,583 kernels for the first cutting to 246 for the last cutting.

The quantitative method used for separating the proteids was that described in Bulletin 42 of the station (*E. S. R.*, 8, p. 854), except that in the extraction of the gliadin alcohol of 0.9 sp. gr. (about 58 per cent by weight) was used instead of 75 per cent alcohol, as formerly recommended. The nitrogen compounds were determined in each of the 42 samples of wheat ripened on the straw; the nitrogen was determined in the grain of the heads cut from the straw for the first 36 days, and a complete determination of the nitrogen compounds of the third sample of this series was made. These data are tabulated on the basis of dry matter and of total nitrogen, and the differences in composition where the heads were cut from the straw and the grain cured on the straw are given. A summary of the nitrogen compounds for groups of 3 days is given in the following table:

Nitrogenous compounds in wheat at different stages of maturity, in percentages of the total nitrogen.

Period.	Stage of maturity	Gliadin nitrogen.	Glutenin nitrogen.	Edestin and leucosmin nitrogen.	Amid nitrogen.
1	A little past bloom; grain set.....	28.4	44.2	11.9	15.5
2	Berries one-half to full length of ripe grain.....	34.7	43.1	13.7	8.5
3	Grain coming in milk; lower leaves dying.....	39.9	37.8	15.1	7.2
4	Grain well in milk.....	41.9	36.2	15.2	6.7
5	Heads and kernels well developed; thin dough.....	43.3	35.7	14.7	6.3
6	Grain in dough.....	45.6	35.6	13.9	4.9
7	Grain in stiff dough; straw becoming yellow at butt.....	48.5	35.8	11.4	4.3
8	Straw much yellowed but still decidedly green.....	50.0	35.9	10.3	3.8
9	Straw still a little green.....	53.5	32.7	10.4	3.4
10	Wheat fit to cut; berry nearly dry.....	53.3	31.5	11.8	3.4
11	Grain overripe.....	51.9	33.2	11.6	3.3
a (11)do.....	(52.9)	(32.4)	(11.5)	(3.2)
12do.....	53.5	31.1	11.5	3.9
13do.....	52.4	32.3	11.1	4.2
14do.....	53.0	31.9	11.3	3.8

a Figures in parentheses give average of group, omitting one sample which was irregular.

"When considered in proportion to the whole amount of nitrogen compounds present, there is a large increase in the gliadin from the earliest cutting of the grain until it is ripened. There is a marked but smaller decrease in the proportion of glutenin over the same time and a very rapid falling off in the proportion of amids during the first few days. The changes in the proportion of edestin and leucosin during the entire time of cutting is less marked and more irregular.

"There is a corresponding but less marked change in these same compounds when considered in percentages of the dry matter of the grain.

"The nitrogen compounds in this grain when ripe were in about the following proportions: Amids 1, edestin and leucosin 3.5, glutenin 10, and gliadin 16.

"There was over the period preceding ripening a very appreciable larger percentage of nitrogen in the wheat of heads cut from the straw at the time of the gathering than in that gathered at the same time and dried on the straw, the explanation of which seems to be that the transfer of dry matter from the straw to the grain after cutting was largely one of non-nitrogenous matter.

"When considered in relation to the whole amount of nitrogen compounds present, there was little difference in the proportions of the different nitrogen compounds in the wheat dried on the straw and in that of heads cut from the straw."

To study the changes in the nitrogenous compounds in the endosperm, samples of the wheat from the sixteenth to the thirtieth cuttings were milled in a small roller flour mill provided for the purpose, and the nitrogenous compounds in the flour determined. The results are tabulated on the basis of the total dry matter and of the total nitrogen, and are compared with those obtained for the whole wheat. These showed that the difference between the total nitrogen in the whole wheat and in the endosperm was very appreciably greater in the ripe wheat than in the wheat cut a week or 10 days earlier. Up to about 2 weeks before ripening the gliadin nitrogen formed a greater proportion of the dry matter of the endosperm than of the whole wheat, but from that time until ripening this was reversed, the proportion of gliadin nitrogen being greater in the whole wheat than in the endosperm.

A study was also made of the proximate composition of wheat at different stages. The samples cut at different stages and dried on the straw were analyzed and the results in periods of 3 days, corresponding to the stages of ripeness mentioned in the preceding table, are given as follows:

Proximate composition of wheat at different stages, calculated to dry matter.

Period.	Ash.	Pro- teids.	Amids.	Fats.	Crude fiber.	Pento- sans.	Dex- trins.	Su- crose.	Dex- trose.	Starch and un- deter- mined.

"The proportions of ash, amids, fats, fiber, dextrins and pentosans gradually decreased in the dry matter of the grain from the earliest stages up to ripeness. The proportion of sacrose rapidly decreased for the first 5 periods and was practically constant from then on. The very appreciable quantity of reducing sugar in the earlier periods decreased to a mere trace up to the time of ripening. The proportion of starch rapidly increased up to a week or more before ripening.

"The proportion of total proteids in the dry matter of the grain steadily decreased from the earliest time up to about a week before ripening and gradually increased from then on. This is not in accord with results of Dr. Kedzie¹ in experiments of 2 different years in Michigan, and it is hoped that further information on the subject may be obtained from work now in progress on another year's growth of Arkansas wheat."

Summary of experiments with corn and wheat, 1898 (*Oklahoma Sta. Bul. 36, pp. 4*).—The results of experiments with wheat and corn are briefly stated. Among the varieties of wheat tested Fultz, Red Russian, and Fulcaster gave the best yields, the average for 2 years being 45, 42, and 41 bu. per acre, respectively. Early Red Clawson, Big English, Missouri Blue Stem, Sibley New Golden, Mealy. Crate, and Lebanon averaged from 35 to 40 bu. per acre; and Dietz Longberry, Nigger, Bearded Monarch, German Emperor, Extra Early Oakley, Longberry, Miami Valley, Early Ripe, Saskatchewan, and Valley from 30 to 35 bu. per acre. Genesee Giant was most affected by rust. In general wheat sown September 25 or October 5 gave better returns than wheat sown earlier or later. The results from sowings at the rates of 3, 4, 5, 6, and 8 pk. per acre showed that in general the average yield increased from thinnest to thickest seeding. Rolling the land in addition to harrowing it before seeding produced no appreciable effect.

In general the best results in the experiment with corn were obtained from plantings made March 28, with kernels every 12 in. in rows 3 ft. 8 in. apart; and from plowing about 6 in. deep and subsoiling 4 in. lower. A root-pruning experiment showed that no injury resulted from running a knife 3 in. deep, or running it 6 in. deep 22 in. away from the plants. Where the knife cut 6 in. deep within 6 or 12 in. of the stalk the yield was reduced considerably. The results from different methods of cultivation proved inconclusive. Brazilian Flour corn and Cornucopia yielded 21 and 15 bu. per acre, respectively. In all experiments except the variety test, Adams White Dent corn was grown, and some plats yielded from 40 to 60 bu. per acre.

Experiments with roots and forage crops, F. W. RANE (*New Hampshire Sta. Bul. 57, pp. 127-153, figs. 14*).—This bulletin describes in a popular manner the cultural tests made at the station of various root and forage crops and gives recommendations for their culture. The following crops were grown: Ensilage corn, millets, Brazilian flour corn, teosinte, Kafir corn, millo maize, Jerusalem corn, soy beans, cow-peas, Russian vetch, oats and Canada peas, crimson clover, lupines, serradella, sainfoin, rape, kale, spurry, sunflower, Idaho field pea, sachal-

¹Michigan Bd. Agr. Rpt. 1881-82, p. 233; reprinted 1885, p. 121; and Michigan Sta. Bul. 101 (E. S. R., 5, p. 782).

line, giant beggar weed, sugar beets, carrots, ruta bagas, mangel-wurzels, turnips, and Jerusalem artichokes. The millets, *Panicum crus-galli*, *P. mileacea*, *P. italica*, Golden Winter and New Siberian, yielded about 16, 10, 7, 9, and 5 tons of hay per acre, respectively. It was found that soy beans responded readily to fertilizers supplying potash, phosphoric acid, nitrogen, and lime. Of 5 varieties of cowpeas, Southern Yellow Eye produced the best yield—over 18 tons of green material per acre. The average yield of Russian vetch (*Vicia villosa*) was over 13 tons of green fodder per acre. The results with crimson clover have been reported in a former bulletin (E. S. R., 8, p. 586). Thousand-headed kale, sown in spring and cut in August, yielded about 24 tons of green fodder per acre. The yields of the root crops are given in a table.

Forage crops, E. B. VOORHEES and C. B. LANE (*New Jersey Stats. Bul. 130, pp. 1-16, pls. 2*).—The results of experiments with forage crops conducted for 3 years are reported, and the methods used in seeding and the cost and composition of the fertilizers applied are discussed in a popular manner. The following forage crops, arranged in the order of their use during the season, were grown at the station: Rye, crimson clover, red clover, mixed grasses, oats and peas, corn, cowpeas and soy beans, Japanese millet, and barley and peas. The land on which these crops were grown received a general application of 8 tons of barnyard manure per acre annually. In addition to this application the crimson clover, corn, cowpeas, and soy beans received a dressing of 200 lbs. per acre of an even mixture of ground bone, acid phosphate, and muriate of potash; the millets, oats and peas, and barley and peas, an application of 200 lbs. per acre of a mixture of 50 lbs. nitrate of soda, 100 lbs. of acid phosphate, 100 lbs. of ground bone, and 50 lbs. muriate of potash. The cost of the fertilizers for these crops was \$2.50 per acre. The rye received a dressing of 100 lbs. acid phosphate and 50 lbs. muriate of potash per acre, applied immediately before seeding. The cost of this application was \$1.50 per acre.

The digestible food and its cost of production in the various crops as determined in these experiments is given in the following table, the object of the analysis being to determine the average composition of each crop at the stage best fitted for feeding:

Cost and amount of digestible food in various forage crops.

Kind of crop.	Dry matter per ton.	Digestible food per ton.			Nutritive ratio.	Cost per ton
		Fat.	Protein.	Carbo-hydrates.		
Legumes:	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>		
Crimson clover	322	5.4	49.6	148.4	1: 3.3	\$0.61
Barley and peas	316	8.6	45.2	118.4	1: 3.1	1.56
Oats and peas	360	10.8	42.8	160.4	1: 4.4	1.04
Soy beans	385	6.6	34.2	174.0	1: 5.6	1.20
Cowpeas	258	6.0	28.8	119.0	1: 4.6	1.06
Cereals:						
Rye	362	8.8	41.0	205.6	1: 5.5	.68
Broom-corn millet	360	7.6	34.6	171.4	1: 5.5	.73
Italian millet	541	10.6	30.8	295.6	1: 10.4	.88
Corn	458	8.2	19.8	287.6	1: 15.5	.78
Barnyard millet	269	4.0	18.8	134.2	1: 7.7	.83

Only one sample of barnyard millet was secured, and it is believed that the analysis does not fairly represent its average composition.

The average cost of production was 75 cts. per ton for the cereal crops and \$1.33 per ton for the leguminous crops, exclusive of the crimson clover.

A study was made of 2 soiling crop rotations, and the results are reported in detail. Both proved exhaustive to the soil. The method of fertilization followed in the experiments as described above is recommended.

The lodging of grain, JULIEN and DUPONT (*Ann. Agron.*, 21 (1898), No. 11, pp. 534-548).—A study was made of the lodging of grain in the experimental fields at Grignon, where 2 plats of wheat lodged June 25 after violent rain and wind storms had prevailed, while the grain on 2 other plats remained intact. The conditions were the same for all these plats. It was found that the lodged grain had been attacked by 2 fungus diseases, *Erysiphe graminis* and *Ophiobolus graminis*, which weakened the stems and caused them to lodge. Of the lodged plants 15 per cent failed to ripen their grain, while of those which remained standing only 1 per cent failed to produce ripened grain. Grain had lodged in previous years on the plats which produced the lodged grain this season, and the authors believe that the spores which remained in the soil germinated under favorable conditions and caused the spread of the disease and the ultimate lodging of the grain. Burning the stubble after the grain has been harvested is recommended as a remedy.

The yield and composition of the lodged and unlodged grain were compared. It was found that wheat and oats were similarly affected by lodging. The composition of the harvested grain from the lodged and the unlodged plats was about the same, but the kernels on the lodged plat were reduced in number and in weight, thus diminishing the yield considerably.

The stooling of grains, B. C. BUFFUM (*Wyoming Sta. Bul.* 37, pp. 207-242, pls. 2).—Experiments to determine the relative tillering of wheat, oats, and barley were carried on at Laramie and at 4 substations in the State for 2 years in succession.

In 1896 seeds were planted 1, 2, 4, and 12 in. apart in rows 3 ft. apart; and in 1897 the experiment was repeated on a somewhat larger scale. In addition to these tests small plats were planted with different amounts of seed per acre to determine results in actual field practice.

The results are tabulated and discussed and also presented graphically. The effects of altitude and irrigation on the stooling of grains are discussed, and some practical hints in grain growing at high altitudes are given.

In general the results show that the number of mature heads produced by each seed varies greatly with the locality and the season, and that the number of heads and the amount of grain produced increases rapidly with the space given each seed. It was found that plants

grown at wide distances apart produced shorter straw and a greater proportion of straw to grain than when thickly planted.

"Where given too much room many more stems are produced than will mature heads. On account of the continuous growth from the crown of the stool during the summer the grain is late in maturing, does not fill well, and as a whole produces light, inferior grain.

"Larger heads are produced upon grain planted more than 1 in. apart, although all the heads may not be as uniform in size. The number of seeds in the largest heads produced increased rapidly with the distance between plants.

"While more grain will be produced by each seed when planted at greater distances than 1 in. apart, the actual amount of grain will be less for the area of land used . . . A study of our experiments seems to indicate that in farm practice sowing seed so plants will be secured about 1 in. apart in the drill will produce the largest yields per acre of wheat or barley, but that oats should probably be planted a little thicker than this."

The author concludes from his investigations that if 80 per cent of the seed germinates and it is sown in drills 8 in. apart, it requires 78 lbs. of wheat weighing 61 lbs. per bushel, 86 lbs. of barley weighing 53 lbs. per bushel, and 61 lbs. of oats weighing 40 lbs. per bushel to plant an acre with plants 1 in. apart in the row.

At Laramie in 1897 50 and 70 lbs. of wheat per acre gave as large yields as greater amounts of seed, but where 100 lbs. per acre were sown the grain weighed more per bushel and ripened earlier. There was little difference in the yield of barley plats sown at different rates per acre, but the plats with the heavier seeding ripened earlier and produced better grain. Oats seeded at the rate of 60 lbs. per acre gave the best yield. The thinly seeded plats failed to ripen the grain fully. At Sheridan in 1897 the best yields were obtained from sowing 50 to 70 lbs. of wheat, 70 to 80 lbs. of barley, and 80 to 100 lbs. of oats per acre. The results obtained at the 5 different places indicate that barley has the greatest tillering power, followed by wheat and oats in the order mentioned.

"In addition to the importance of thicker seeding at high altitudes to shorten time of ripening, our experiments indicate that upon like soils and under similar climatic conditions, wheat, oats, and barley actually produce less matured heads and less grain with increase of altitude.

"Grain under irrigation produced more matured heads per stool and more grain than where raised without irrigation. . . .

"The amount of grain produced on different amounts of seed per acre varies in different seasons. On account of increased tillering light seeding (from 30 to 50 lbs. per acre) may produce as much grain as would a larger amount of seed; but when more seed is sown the difference in weight of the grain per bushel, along with shorter period of maturity and evenness in ripening, may more than pay for the extra seed used.

Trials with orchard grass, F. AND K. HANSEN (*Landmansblade*, 31 (1897), No. 10, p. 134).—Experiments were conducted for 10 years at 3 Danish experiment stations for the purpose of ascertaining the amount of hay obtained from orchard grass, the seed of which had been obtained from different sources. The average results at the 3 stations are con-

pared in the following table, the yields from American seed being placed at 100:

Culture tests with orchard grass.

Source of seed.	Location of experiment station.		
	Tystofte.	Askov.	Lyngby.
America (United States)	100	100	100
Europe (Denmark, Germany, France, Sweden).....	98	102	97
Australia and New Zealand.....	78	85	74

—F. W. WOLL.

Influence of permanent grass culture on the nitrogen content of the soil compared with that of other crops. T. A. TUXEN (*Norsk. Landmandsblad*, 17 (1898), No. 13, p. 112).—The experiments were conducted at the State Agricultural College at Copenhagen to determine the influence of continued grass and barley culture and crop rotations on the nitrogen content of the soil. The plats were divided into 3 series; the first was left unmanured, the second received regular applications of complete commercial fertilizers, and the third was regularly manured with barnyard manure. The quantity of nitrogen in the soil was determined after the experiment had been in progress 22 and 30 years. The average results are given in the following table:

Nitrogen per hectare in the upper twenty centimeters of soil on plats under different systems of cropping.

	Plats cropped for 22 years.			Plats cropped for 30 years.		
	No ferti- lizer.	Commer- cial fer- tilizer.	Barnyard manure.	No ferti- lizer.	Commer- cial fer- tilizer.	Barnyard manure.
	Kgs.	Kgs.	Kgs.	Kgs.	Kgs.	Kgs.
Continuous grass culture	4, 931	5, 131	5, 842	4, 638	5, 010	6, 793
Continuous barley culture	3, 578	3, 639	4, 596	3, 479	3, 403	4, 804
Cropping in rotation.....	4, 407	4, 582	5, 493	5, 025	5, 185	6, 164

The results show the beneficial effects of grass crops on the nitrogen content of the soil compared with continuous barley culture, and rotative cropping. The grass plats which received commercial fertilizers or which were left unmanured gave less favorable results after 30 years of cropping than the plats on which various crops, including beans, were grown in rotation. It is concluded that commercial nitrogenous fertilizers do not increase the nitrogen content of the soil to the same extent as barnyard manure.—F. W. WOLL.

Field experiments with fertilizers in 1897 (*Ohio Sta. Bul. 94*, pp. 291–326, *dgms. 2, map 1*).—The plan of these experiments, the soils upon which they were conducted, and the results obtained up to the end of 1896 have been described in previous bulletins (*E. S. R.*, 8, p. 576; 9, p. 747). In this bulletin the results obtained in 1897 are tabulated and discussed and conclusions drawn.

It was found that for the crops under test, corn, oats, wheat, clover, timothy, and potatoes, and for the soils upon which they were grown, phosphoric acid was the most important fertilizer constituent, with nitrogen and potash following, in the order named. The largest increase in yield was obtained with the complete fertilizers containing all these constituents, but it is believed that the use of nitrogen and potash in the same proportion to phosphoric acid in which they are found in the crops is unnecessary under present conditions, and that the quantity of phosphoric acid should considerably exceed that of either nitrogen or potash in applications for corn, oats, or potatoes, while for wheat the proportion of nitrogen may closely approximate that of phosphoric acid. Dissolved boneblack seemed more effective than raw bone meal or acid phosphate; basic slag stood next to it in effectiveness.

"Nitrate of soda is apparently the most effective carrier of nitrogen in common use as a fertilizer. . . . Slaughterhouse tankage . . . is probably a less effective carrier of nitrogen than nitrate of soda, but the cost of nitrogen in unmixed tankage when due allowance is made for the phosphoric acid carried by the tankage is so much less than in nitrate of soda that tankage becomes a much more economical source of nitrogen to the Ohio farmer than nitrate of soda.

"This advantage in tankage disappears, however, when it is purchased in the ordinary factory-mixed fertilizer, since the price at which such fertilizers are generally sold brings the cost of their nitrogen to a higher figure than its necessary cost in nitrate of soda."

The results further show that the phosphoric acid of finely ground bone meal and tankage is as effective as the available phosphoric acid of acid phosphate, and that when these materials are finely ground no further treatment with sulphuric acid is necessary to render their phosphoric acid available.

The fertilizing constituents of barnyard manure acted more slowly than those of commercial fertilizers, but as they cost much less in manure it became the cheapest fertilizer. Applying manure to the surface instead of plowing it under proved to be most advantageous.

"The increase from fertilizers in these experiments was unusually large in 1897, this being the first season of the experiments at this station in which the cereal crops have given a general increase sufficient to cover the cost of fertilizers. In the average of the 4 seasons . . . the value of the increase of crop has only equaled the cost of the fertilizer in a few instances. The most profitable increase in the average is found in the crop which has received a fertilizer mixed from tankage and acid phosphate, with a small addition of muriate of potash, used only on corn and wheat."

Third report on potato culture, I. P. ROBERTS and L. A. CLINTON (*New York Cornell Sta. Bul. 156, pp. 175-184*).—This work is in continuation of experiments now in progress for 4 years. Previous results have been reported in former bulletins (*E. S. R.*, 9, p. 345 and p. 1044). The results for 1898 are reported, and the soil conditions, the various operations, and other details of the experiment are described. Directions for making Bordeaux mixture are given, and the ferro-cyanid of potassium test for the purpose of determining the amount of lime

required is recommended. The records of the experiment for this season were as follows:

Records of potato plats for 1898.

Variety.	Date of planting.	Number of cultivations.	Number of sprayings.	Date of digging.	Yield per acre.
					<i>Bushels.</i>
Endurance	May 10 ..	6 level ..	7 ..	October 18	398.6
Carman No. 3	do ..	6 level ..	7 ..	do ..	344.8
Do	do ..	3 level ..	7 ..	do ..	303.3
Do	do ..	3 level ..	7 ..	October 17	340
Do	do ..	3 hilled ..	7 ..	do ..	327.5
Do	do ..	6 level ..	7 ..	September 29	310.5
Do	do ..	3 level ..	7 ..	do ..	269.6
Do	do ..	3 level ..	7 ..	do ..	269.8

Rose of Sharon	do ..	6 level ..	7 ..	do ..	118.6
Endurance	do ..	6 level ..	0 ..	do ..	232

The following conclusions are based on the results obtained during 4 years:

"Early planting of potatoes and frequent tillage to conserve moisture will ordinarily give best results, [but] necessitates vigorous spraying with Bordeaux mixture and Paris green to protect the foliage from blight and beetles.

"Success with potatoes depends largely upon the preparation given the soil before the potatoes are planted. Plowing should be deep and at the time of planting the soil should be mellow and loose.

"On soils which are likely to be affected seriously by droughts, it is especially important that the potatoes be planted early and deep, and the tillage should be frequent and level.

"On soils which are not well drained, either naturally or artificially, and on clay or clay-loam soils, potatoes may be planted somewhat shallow and slight hilling may be practiced with benefit.

"Harrowing the land after the potatoes were planted and before the plants appeared produced marked beneficial results. From 6 to 7 cultivations have given best yields."

Variety test of potatoes, C. O. FLAGG, G. M. TUCKER, and J. A. TILLINGHAST (*Rhode Island Sta. Rpt. 1897, pp. 381-388*).—The method of carrying on the test is described and the results are given in tabular form. Brief descriptions are given of the new varieties used in the experiment.

In 1896, 11 varieties of potatoes were tested, and the following season 5 of these varieties were given a further trial and 10 new varieties were grown in addition. Enormous, a late variety, produced the largest total yield and marketable crops in both seasons.

Cultural experiments with potatoes, C. O. FLAGG, G. M. TUCKER, and J. A. TILLINGHAST (*Rhode Island Sta. Rpt. 1897, pp. 322-351*).—The results reported show the effects on the yield of potatoes (1) of spading the soil to depths varying from 4 to 18 in., (2) of very thorough and less thorough cultivation, and (3) of planting at varying distances. The experiments were conducted for 2 years in succession. The aver-

age results for 2 seasons obtained with plats spaded at different depths are given in the following table:

Average yields of potatoes from plats spaded to different depths in 1896 and 1897.

Depth of spading.	Yield per acre.		
	Total yield.	Large tubers.	Small tubers.
4 inches.....	<i>Bushels.</i> 288.38	<i>Bushels.</i> 158.85	<i>Bushels.</i> 129.52
8 inches.....	297.65	186.70	110.92
12 inches.....	286.34	180.32	106.37
15 inches.....	289.89	187.55	102.33
18 inches.....	300.22	187.34	112.88

In the cultivation tests the soil of a number of plats was worked to a depth of about 2 in. 10 times the first year and 8 times the second, while an equal number of plats were cultivated 4 in. deep 11 times in 1896 and 10 times in 1897. The average results show that less thorough cultivation gave an excess of 4.75 bu. per acre in total yield and 6.68 bu. in large tubers over more thorough cultivation, while the latter gave an excess of 2.1 bu. of small potatoes per acre as compared with the former.

In 1896 seed pieces uniform in size were planted 9, 12, and 16 in. apart in drills 24 and 30 in. apart. After deducting the seed from the yield of large tubers the plants grown 9 in. apart in the row yielded at the rate of 192.99 bu. per acre of large tubers or 6.52 bu. more than the 12 in. planting and 19.56 bu. more than the 16 in. planting.

In 1897 the results were the reverse of those obtained in 1896. The yield of large tubers increased with the distance between plants in the drill. The average yield of large tubers was 36.29 bu. per acre more in drills 24 in. apart than in drills 30 in. apart.

Further tests of seed potatoes grown one or more years in Rhode Island from northern-grown seed tubers, C. O. FLAGG and J. A. TILLINGHAST (*Rhode Island Sta. Rpt. 1897, pp. 371-380*).—These tests are in continuation of work formerly reported (*E. S. R., 9, p. 943*). A description of the experiments is given and the results for the entire series are reported in tables. The author summarizes the results as follows:—

“The average yields of 7 varieties of potatoes, home-grown respectively 2, 3, and 4 years from seed tubers, produced in Aroostook County, Maine, show great uniformity. The heaviest average total yield was in the second-year crop, while the heaviest yield of large potatoes was in the fourth-year crop.

“The average weight of the tubers produced was lowest in the case of the second-year crop and highest in the fourth-year crop. The percentage of large tubers by weight was greatest in the case of the fourth-year crop.

“The variety producing the heaviest crop gave the greatest yield secured in the test as the product of the fourth-year crop, viz, 245.87 bu. per acre; and the variety which gave the lowest yield, 155.84 bu. per acre, produced the smallest yield of the test as the product of the fourth-year crop.

"Varieties which produced the larger yields gave increased crops the longer the seed tubers had been home-grown, while those which produced smaller crops gave decreasing yields the longer the seed had been home-grown."

The potato crop in the rotations, C. O. FLAGG, G. M. TUCKER, and J. A. TILLINGHAST (*Rhode Island Sta. Rpt. 1897, pp. 389-393*).—Six rotations are in progress in 2 of which potatoes are planted on clover sod while in the other 4 they are planted after corn. The results for the seasons of 1896 and 1897 are reported. The average results indicate that when potatoes are planted on a clover sod a better yield is obtained than when the crop is planted after corn. "The growth of potatoes upon the clover-sod plats was very rapid and vigorous, indicating the presence in the soil of considerable available nitrogen."

External indication of an increase of solanin in potatoes, SCHNELL (*Apoth. Ztg., 13 (1898), p. 775; abs. in Chem. Ztg., 22 (1898), No. 95, Repert., p. 291*).—In examining potatoes which had caused wholesale sickness among soldiers, the author found small gray spots which were richer in solanin than the white part of the potato. Whether these gray spots were due to the action of fungi or bacteria he was unable to determine. The potatoes had sprouted vigorously early in June, and contained about 6 times the normal amount of solanin.

Fertilizer experiments with potatoes, C. O. FLAGG, G. M. TUCKER, and J. A. TILLINGHAST (*Rhode Island Sta. Rpt. 1897, pp. 352-373*).—The fertilizer experiments with different amounts of nitrogen, phosphoric acid, and potash for potatoes made in 1896 and 1897 are described and the results tabulated and summarized. The total rainfall for May, June, July, and August is reported as 14.71 in. in 1896 and 19.04 in. in 1897. The standard fertilizer used in these experiments as a base upon which comparisons were made consisted of muriate of potash, dissolved phosphate rock, and nitrate of soda. It was applied at the rate of 1,678.51 lbs. per acre, and contained 3.2 per cent nitrogen, 8 per cent of available phosphoric acid, and 6.48 per cent of potash. The standard application was the same for both seasons, but the amount of the different elements of plant food varied on certain plats, being one-half, 2, and 3 times the amount furnished in the standard fertilizer application. When the amount of an element in the application was increased or decreased the other elements were supplied as in the standard fertilizer. The materials used for fertilizers and the amount of the standard applications are given in the following table:

Fertilizers used and the standard application of each.

Fertilizer.	Standard application per acre.	
	1896.	1897.
	<i>Pounds.</i>	<i>Pounds.</i>
Muriate of potash	207	214.89
Sulphate of potash	209	226.51
Dissolved phosphate rock	1,080	374.10
Nitrate of soda	392	343.39
Dried blood.....	452	438.50

The average results for the 2 years show that the largest total crop and the largest yield of large tubers was produced when the supply of potash was half sulphate and half muriate. The standard application of muriate of potash gave a better average yield of total product of large and small tubers than an application containing double the amount of potash. The tests with different amounts of phosphoric acid resulted in the smallest average yield from the standard application, the next largest from the use of 3 times the amount of phosphoric acid furnished in the standard fertilizer, and the largest yield—an increase of 15.93 bu. per acre of marketable potatoes over the standard application—from a fertilizer which contained twice that amount of phosphoric acid. The amount of phosphoric acid which proved the most effective cost \$6.29 more per acre in 1897 than the amount in the standard application. The average results in the comparison of nitrate of soda and dried blood as carriers of nitrogen show that nitrate of soda was most effective, followed by dried blood, and an application of half of each in the order mentioned. The difference in the average of the crops of the nitrogen plats was not great, the extremes in the marketable tubers being 165.35 and 173.4 bu. per acre.

Trials with fish guano for sugar beets, P. HANSSON (*Meddel. K. Landtbr. Styr., 1897, No. 42, pp. 149, 150*).—Fish guano and nitrate of soda were applied in corresponding quantities on 6 plats, 3 of which received fish guano and 3 nitrate of soda. On clay humus the relation of the effect of nitrate of soda to that of fish guano was as 100 to 80; on moist humus, as 100 to 90, and on dry, porous, and sandy humus as 100 to 120.—F. W. WOLL.

Fish guano vs. nitrate of soda for sugar beets and for barley, C. O. HAMMARGREN (*Meddel. K. Landtbr. Styr., 1897, No. 42, pp. 145, 146*).—Comparative experiments with fish guano and nitrate of soda for sugar beets and for barley were made on eighth-acre plats. The results obtained are given in the table:

Results of fertilizer experiments with sugar beets and barley.

Sugar beets.				Barley.			
Fertilizers per hectare.	Yield per hectare.		Fertilizers per hectare.	Yield per hectare.

—F. W. WOLL.

Report of the agriculturist, H. E. STOCKBRIDGE (*Florida Sta. Rpt. 1898, pp. 11-21*).—In this report the station farm is described and contemplated experiments are outlined. Bulletin No. 44 of the station is reviewed (E. S. R., 10, p. 347). Directions

are given for making a "simple sirup tester," an instrument for determining the variations in density or the thickness of sirup for the use of ordinary workmen.

The necessity of practical field tests and the methods of conducting them, LOGES and VIBRANS (*Jahrb. Deut. Landw. Gesell.*, 11 (1898), pp. 65-74).—A paper read before the German Agricultural Society.

Beet culture and beet seed production, P. DOERSTLING (*Bl. Zuckerrübenbau*, 6 (1899), No. 4, pp. 57, 58).—A brief note referring to some of the results of interest in this connection obtained by several investigators.

Time of harvesting beet seed, NOBBE (*Jahrb. Deut. Landw. Gesell.*, 13 (1898), pp. 189-197, fig. 1).—This paper discusses the practices of a number of prominent beet seed growers and gives the results of germination experiments with beet seed carried on in 1896 and 1897. The author concludes from the results that under favorable weather conditions it is best to allow the seed to ripen in the field.

The importance of growing cereals and catch crops, STIEGER (*Fühling's Landw. Ztg.*, 47 (1898), No. 20, pp. 762-764).—The importance of cereals and catch crops in rotations is discussed.

Cotton and its by-product (*Jour. Jamaica Agr. Soc.*, 3 (1899), No. 3, pp. 133-137).—A popular article on the cultivation and uses of cotton.

Flax culture in the Russian Baltic provinces and in Germany, SCHINDLER (*Jahrb. Deut. Landw. Gesell.*, 13 (1898), pp. 177-184).—A paper comparing the cultural methods of the two regions.

Hop culture, REMY (*Fühling's Landw. Ztg.*, 47 (1898), No. 19, pp. 730-733, 756-758).—An article on the use of hops for brewing purposes. The author considers the chemical composition and the aroma of hops and discusses the methods of harvesting and drying.

Investigations on the effects of drying hops by fire heat, T. REMY (*Wchuschr. Brau.*, 14 (1897), No. 53, pp. 682, 683).

Report on the culture experiments of the German potato experiment station in 1898 (*Sächs. Landw. Ztschr.*, n. ser., 21 (1899), No. 8, pp. 81-87; *Deut. Landw. Presse*, 26 (1899), No. 19, pp. 196, 197).—A report on cooperative tests of new varieties of potatoes on 26 experiment fields located in different parts of Germany.

Variety tests of potatoes, 1898, TANCRÉ (*Landw. Wehnl. Schleswig-Holstein*, 49 (1899), No. 10, pp. 166-171).—Tabulated results of cooperative variety tests of potatoes are given, with brief notes on the different experiment fields. Brief descriptions are given of some of the varieties.

The culture of potatoes on the experimental field at Grignon in 1896 and 1897, J. CROCHETELLE (*Ann. Agron.*, 24 (1898), No. 1, pp. 39-48).

Experiments with potatoes, F. DESPREZ (*Jour. Agr. Prat.*, 1899, I, No. 9, pp. 314-316).—A résumé of the results of variety tests, distance experiments, and experiments in hastening the maturity of late varieties is given.

Ruta-bagas, H. L. DE VILMORIN (*Jour. Agr. Prat.*, 1899, I, No. 9, pp. 319-323, pl. 1).—This article discusses the origin and history of the ruta-baga, describes a number of different varieties, and gives directions for the culture of the crop.

Breeding Pirnaer rye and investigations on rye breeding in general, STEGLICH and FISCHER (*Jahrb. Deut. Landw. Gesell.*, 13 (1898), pp. 198-210).—This paper describes the method in which the Pirnaer rye was originated, and gives the results of experiments in growing rye from different colored grains and from seed taken from plants with different numbers of internodes. It was found that grains grayish green in color were richer in nitrogen than reddish yellow or dark brown grains.

Sugar cane from seeds in the Straits Settlements, C. CURTIS (*Agr. Bul. Malay Peninsula* [Bot. Gard. Dept. Straits Settlements], 1898, No. 8, pp. 219-221, pl. 1).—A popular article on growing sugar cane from seeds.

Preparation of seed beds for tobacco plants (*Würt. Wehnl. Landw.*, 1899, No. 10, p. 142).—A popular note.

Culture and fertilizer experiments with tobacco, DETTINGER (*Ztschr. Landw. Ver. Rheinpreussen*, 15 (1898), No. 31, pp. 281-283).—The results of cooperative experi-

ments are reported. The plats on which the tobacco was grown were bedded and this method of culture gave good results. The use of commercial fertilizers gave as good results as the use of barnyard manure. The use of guano proved detrimental to the quality.

Report on variety tests, EDLER (*Jahrb. Deut. Landw. Gesell.*, 13 (1898), pp. 184-189).—This report contains brief notes on the results of tests with 13 varieties of spring wheat, 11 of winter wheat, 23 of square-head wheat, and 1 variety of lupines.

The relation of crop rotation to fertilization, SCHULTZ and MAERCKER (*Jahrb. Deut. Landw. Gesell.*, 13 (1898), pp. 31-47).—A paper read before the German Agricultural Society.

Green manuring and its extension in Bavaria with reference to soil, climate, and other conditions, SCHNIDER (*Vrtljsschr. Bayer. Landw. Rath.*, 3 (1898), No. 4, pp. 459-478).—This article discusses the value of various plants for green manuring and suggests 8 different crop rotations for the improvement of soils.

Green manuring and fallowing on heavy soils, W. EDLER (*Fühling's Landw. Ztg.*, 47 (1898), No. 22, pp. 841-847; 23, pp. 870-880).—Comparisons of green manuring and fallowing on heavy soils were made and the results are here given in tables and discussed. In general the results were in favor of fallowing, even when peas were used for green manuring. The author believes fallowing preferable to green manuring on heavy soils, as sowing of fall catch crops is often unsuccessful and as these soils are usually not poor in nitrogen.

Report on fertilizer experiments in 1897-98, TANCRÉ (*Landw. Wechubl. Schleswig-Holstein*, 49 (1899), No. 8, pp. 132-135).—The results of cooperative fertilizer experiments are given.

HORTICULTURE.

Garden lettuce and its cultivation, L. F. KINNEY (*Rhode Island Sta. Rpt.* 1897, pp. 270-285, figs. 8).—In this article the author speaks of the favorable location and climate of Rhode Island for lettuce growing, and discusses the modification of form of garden vegetables due to cultivation. The frequent failure of lettuce to head is attributed to the "inability of the plants to absorb or to assimilate an adequate amount of nutritive substances. The former is usually due to an insufficient amount of available fertilizing ingredients in the soil, and the latter to an insufficient amount of light."

The cultivation of lettuce in the open air is considered. "The ordinary garden fertilizers are adapted for the production of lettuce, but two or three times as much of them should be applied as is necessary for the growth of beets, cabbages, and most other garden vegetables." The development of lettuce cultivation under glass during the last 50 years is sketched. Directions are given for starting the plants, preparing the soil, and for the general care of the crop, especially in regard to temperature, watering, and diseases and injuries. The following varieties are the ones generally grown in Rhode Island: White-seeded Tennis Ball or Boston Market, Big Boston, and another variety resembling the Big Boston. The preparation of lettuce for market is also considered.

Classification and description of the varieties of garden lettuce, L. F. KINNEY (*Rhode Island Sta. Rpt.* 1897, pp. 286-316, figs. 28).—The author believes that the characters of such plants as the garden lettuce

are sufficiently permanent to warrant a systematic classification of the varieties, and that "where both characters and names are associated together for long periods, a systematic classification is just what is needed to obviate confusion." Over a thousand plantings with seeds from different sources were made at the station. Of the kinds of lettuce in existence none, in the opinion of the writer, satisfactorily fulfills the requirements of a forcing variety. Sixty-nine varieties of lettuce are described and classified according to certain botanical characters, as the margin of leaves near the apex, the length of leaves as compared with the width, the color of leaves and seeds, the habit of leaves in regard to head formation, and the apex of leaves. An analytical key to the varieties is given.

Some experiments in forcing head lettuce, S. A. BEACH (*New York State Sta. Bul. 116, pp. 151-179, pls. 4*).—Tests of various soils and fertilizers for forcing head lettuce were carried on during three winters. The forcing house is described and the general treatment of the crops is given with considerable detail. Salamander lettuce was used in the first test and Rawson New Hothouse in the succeeding tests. At first a soil mixture, which had been used for forcing lettuce with good results, composed of 3 parts rotted clay loam sod, 1 part sand, and 1 part stable manure, was compared with soils differing from it only in containing various amounts of sand. In later tests the percentages of sand and clay loam in the soil mixtures were still further varied, the sand in one case and the loam in another being omitted entirely. In some tests a light, sandy loam was compared with the clay loam as a basis of soil mixtures. The amounts of stable manure were varied somewhat in the different tests. Commercial fertilizers in varying amounts were tested in some of the soil mixtures, both in combination with stable manure and alone.

Several tables are given in which are presented such data as the percentages of the different ingredients of the various soil mixtures, the fertilizer elements of the various mixtures and soils used as basis of the mixture, the mechanical elements of the soil in the mixtures, the amounts of fertilizers employed, the time required for the germination of the seeds, the percentage of germination, the size of seedlings, the time required for plants to mature, the average weight of heads, the percentage of marketable heads, the amount of tip burn, the texture, appearance, and firmness of heads, etc.

The author gives the following summary of results:

"The clay loam with a heavy application of stable manure gave the best results. The light, sandy loam with heavy application of stable manure was least satisfactory.

"On pure sand with a good dressing of stable manure the lettuce made a vigorous growth, but the heads were less firm and the texture more delicate than with the lettuce which was grown on the clay loam. . . .

"On clay loam mixed with 15.5 per cent stable manure by weight a slight increase in growth followed the use of nitrate of soda, but with double this application of manure practically no advantage followed the use of nitrate of soda, either on the clay loam or on the sandy loam.

"No advantage was gained either on the clay loam or the sandy loam from the addition of sulphate of potash and acid phosphate when the soils had already received a heavy application of stable manure.

"Excellent lettuce was produced on the sandy loam by using commercial fertilizers with no stable manure.

"A heavy application of stable manure to the sandy loam put the soil in poor mechanical condition and a crop of inferior lettuce resulted.

"The mechanical condition of the clay loam was improved by a heavy application of stable manure. This mixture produced much better lettuce than was grown on the clay loam where commercial fertilizers were used instead of stable manure."

Pea canning in Delaware, G. H. POWELL (*Delaware Sta. Bul. 41, pp. 16, figs. 5*).—This bulletin treats the subject from the commercial point of view. Directions are given for the culture of peas, especially for the canning factory market, and several details of factory manipulation are given.

The pea-canning industry is of considerable horticultural importance in southern Delaware, representing in 1898 about 2,000 acres of land devoted to the growing of the vines, with a product of 144,000 cases. The varieties of peas most largely used for canning are Alaska, Blue Beauty, and French Canner. Advance and Market Garden are canned to a less extent. Three general systems of sowing are in vogue among growers—broadcasting, the 18-inch drill, and the wide-row systems.

The most troublesome enemy of the growing plants is said to be the sunscald (pea blight, *Ascochyta pisi*), a fungus which attacks the plants just before the blossoming period. "It is possible to infect new ground with the fungus where the pea-vine compost is spread on land that is to precede the pea crop, and our observation has led to the conclusion that the disease is most severe on land used successively for the pea, or on new land which has been treated with the pea-vine compost." Rotation of crops is the fundamental corrective for the trouble.

As to the yield, a fair average return for the majority of growers is 450 to 750 lbs. of shelled peas per acre, worth from \$18 to \$30.

Ginseng—its nature and culture, H. GARMAN (*Kentucky Sta. Bul. 78, pp. 125–156, pls. 10, figs. 2*).—A statement is given of the production and exports of the roots of this plant since 1821, and its history in the State is reviewed at some length. Its use in medicine is commented upon, and a partial analysis of the dried roots, as published in the Annual Report of the station for 1892, is quoted as follows:

Composition of ginseng roots.

	Crude ash.	Nitrogen.	Phosphoric acid.	Potash.	Lime.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Roots	5.278	1.660	0.535	0.776	0.856
Ash			10.140	14.700	10.140

The botany of the species is treated at considerable length and directions given for the cultivation of the plant. The price per pound is

given for different counties in the State, in which it appears that the price varies from \$1 to \$4 per pound for dried roots.

Impressions of our fruit-growing industries, L. H. BAILEY (*New York Cornell Sta. Bul. 153, pp. 111-129, fig. 1*).—The bulletin gives a summary of 5 years' study of the actual experiences of fruit raisers in New York to determine the underlying reasons for some of the successes and failures in fruit growing.

“As a result of the inquiries there have appeared, by various persons, 31 bulletins, covering most of the fruits which are commercially grown in the State. In the progress of these investigations it became apparent that there are greater problems in our fruit growing than those of soil and insects and diseases; that fruit growing is profitable or not, in the long run, in proportion as it meets the general requirements of trade and conforms to the agricultural status of the time. It became apparent, also, that even the immediate problems of fertilizers, tillage, and handling of a plantation can not be fully understood from mere scientific investigations at a given place. The investigator must correlate and compare the results of actual fruit growing in many places and under many conditions to be sure that he arrives at broad and sound conclusions, or at principles.”

The tendency in this country to grow but a few varieties is thought to be due to the fact that most American fruit growers are raising fruit for the general market, which requires uniformity of product. The author believes that the tendency is to go too far in the reduction of varieties, thereby reducing fruit growing to a single ideal and increasing competition in one line.

The following are given as the most general causes of barrenness of orchards, stated approximately in order of frequency and importance: “(1) Lack of good tillage, particularly in the first few years of the life of the plantation; (2) lack of humus and fertilizer; (3) uncongenial soils and sites; (4) lack of systematic annual pruning; (5) lack of spraying and of attention to borers and other pests; (6) bad selection of varieties; and (7) trees propagated from unfruitful stock.”

Two experiments with fertilizers are reported. An apple orchard at Lockport was fertilized in August, 1894. The orchard consisted of Baldwin and Greening trees 25 years old and was situated on hard, dry, light clay loam and had been in sod for some time. The trees were unproductive, but looked better than the majority of trees. Some trees received nitrate of soda, others muriate of potash, others sulphate of potash, and others both sulphate and muriate of potash, the materials being scattered as far as the spread of the limbs and lightly plowed under. Tillage was kept up in succeeding years. The first results were seen in 1896, when the trees fertilized with nitrate had much darker foliage, were more vigorous, and produced more fruit than the other trees. In 1897 these trees were still superior to the others, but the difference was not so marked. In 1898 no effect of the fertilizers could be seen.

Another fertilizer test was begun in 1894 in an orchard of Baldwin and King apples near Ithaca. The trees were 25 years old, had been in sod since the first 3 years, but had been well top-dressed with stable

manure for several years, and were in good bearing condition. The orchard was plowed in the fall of 1894 and spring of 1895 and given clean tillage afterward. At the later date sulphate of potash was applied at the rate of 750 lbs. per acre, and in the spring of 1896 the orchard was given a heavy dressing of muriate of potash. In 1895 the apples on the treated trees were larger and from 7 to 10 days later than those on untreated trees. In 1896 the fertilized trees had an unusually dark-colored and vigorous foliage and produced about twice as much fruit as the other trees, the apples being larger, later, and lighter colored. The greater yield was not due to more profuse blossoming, but to less loss from the dropping of fruit. To determine whether the results were due to the cultivation or to the fertilizers, another plat in the orchard was tilled from 1896 to 1898 without fertilizers, and another plat was left in sod, but top-dressed in June, 1896, with 750 lbs. of muriate of potash per acre, and in August, 1897, with 750 lbs. sulphate of potash per acre. The plat which had been cultivated and fertilized since 1894 was continued in cultivation and given sulphate of potash in August, 1897, at the rate of 750 lbs. per acre. The plat receiving cultivation alone and the one receiving fertilizers alone showed no effect of the treatment either in 1897 or 1898. The plat which received both cultivation and fertilizers continued to show better foliage and to produce more, larger, and later fruit than the remainder of the orchard, though the differences were less marked in 1897 than in 1896 and very small in 1898.

The bulletin also discusses the advantages of sod and of clean cultivation, the value of spraying, etc.

Report of the Russian Apple Nomenclature Commission, August 30-31, 1898, N. E. HANSEN (*Minneapolis, 1898, pp. 10*).—This is the report of the first meeting of a commission appointed by the State Horticultural Societies of Minnesota, Iowa, Wisconsin, and South Dakota to revise and simplify the nomenclature of the imported Russian apples. It is well known that among a great number of these are found many well-defined groups or "families." An attempt is made to distinguish these. "The varieties here grouped as members of the same families, while in a few cases differing somewhat in characteristics of tree, are so nearly identical in fruit that for exhibition and commercial purposes they are practically the same and should be so considered." Each group is designated by the name of its most promising variety, which is carefully described. The varieties belonging to the respective groups are enumerated, and incorrect nomenclatures are indicated. The following groups are established: Hibernial, Duchess, Longfield, Charlamoff, Romna, Cross, Christmas, Antonovka, Anisim, Golden White, Repka Malenka, Yellow Sweet, Transparent, and Anis.

In addition to the above, descriptions of the following varieties, which have attracted special attention in the Northwest, were adopted and are published: Long Arcade, Bode, Lubsk Queen, Lowland Raspberry,

Ostrakoff, Vargulek, Sweet Longfield, Beautiful Arcade, Zuzoff, and Arabskoe.

Chemical studies of Oregon fruits: Cherries, G. W. SHAW (*Oregon Sta. Bul.* 55, pp. 12).—This bulletin is a report of progress in the chemical studies of Oregon fruits which was begun in 1896 (E. S. R., 9, p. 753). The cherries grew on the ordinary gray basaltic loam of the Willamette Valley, the average composition of which is given. All were fully ripe when analyzed. Brief notes are given on each variety.

The following table shows the results:

Composition of Oregon cherries.

Variety.	Average weight.	Whole fruit.			Flesh.				Juice.			
		Flesh.	Fibs.	Sugar.	Juice.	Pulp.	Water.	Protein.	Sugar.	Ash.	Acid.	Sugar.
Lincoln.....	4.40	95.45	4.55	8.43	89.53	10.47	82.35	8.83	0.73	9.81

Lewelling.....	4.79	92.31	7.69	11.36	86.00	14.00	74.72	1.00	12.3116	14.30
Rockport Bigar- rean.....	7.79	93.35	6.65	11.78	80.00	20.00	78.65	.84	12.62	.66	.24	15.77
Royal Ann.....	7.26	94.13	5.87	12.85	86.00	14.00	81.29	.88	13.76	.68	.82	16.00
Average.....	5.29	93.92	5.32	10.40	86.35	13.09	81.25	.91	11.21	.53	.43	12.29

The results are compared with those obtained at the California Station (E. S. R., 8, 691), showing that in California the cherry is larger, less juicy, and has a little over 1 per cent more flesh, which the author believes may be explained by the fact that California soils are rich in potash, while those of Oregon are phosphatic. The Oregon fruit has slightly more sugar and protein than the California product, equaling the European analyses as regards the former and exceeding them in the latter. The average acid content from the above table is 0.43 per cent and the ratio between the acid and the sugar in the flesh is 1:26.

“It is interesting to note here that Fresenius gives as the ratio for sweet cherries 1 to 11.16 and for sour cherries 1 to 6.85, calculated as malic acid. This would indicate that a considerable improvement has taken place in those grown on the Pacific coast over those examined by him so far as the proportion of sugar is concerned.”

It is pointed out that the cherry contains considerable nutritive matter, the proportion of dry matter to water being about 1:4.5. Of the dry matter about two-thirds is sugar. The fruit is recommended for drying.

Variety tests of strawberries, raspberries, and blackberries, W. PADDOCK (*New York State Sta. Bul.* 147, pp. 181-198).—This is a report on the relative time of maturity, productiveness, and hardness

of varieties fruited on the station grounds in 1898. These comprise 40 varieties of strawberries, 22 of black raspberries, 26 of red raspberries, and 24 of blackberries. Descriptive notes are given on the strawberries. Of these Anlo, a midseason berry, was first in productiveness, with Stahelin, an early fruit, ranking second. Of the late varieties Rural Gem, Oswego Queen, and Michigan are recommended for trial. Of black raspberries Pioneer and Palmer produce the largest amount of early fruit, with Mills ranking first among the late sorts. Among red raspberries Loudon was the most productive. Among blackberries Success and Meresean are mentioned as promising new sorts.

The European and Japanese chestnuts in the eastern United States, G. H. POWELL (*Delaware Sta. Bul. 42, pp. 35, figs. 12*).—The history of the European and Japanese chestnuts in America is outlined. It is believed that their range will in general coincide with that of the American species. The uses of the nut in France, Italy, Korea, and Japan are stated. Botanically the author prefers to consider the European, American, and Japanese groups as distinct species. Each is described and the synonymy given. Adaptations for cross fertilization are noted, but it is not yet known whether cross fertilization is necessary or not. Mixed planting is recommended as a safeguard. Cultural notes are given. The most serious insect enemy of the chestnut is the weevil (*Balaninus caryatrypes* and *B. rectus*). Methods of combating the pest are suggested. Several fungi attack the chestnut, the most injurious of which are *Marsonia ochroleuca* and *Cryptosporium epiphyllum*. Nine trees in an orchard of Numbos, 20 to 30 ft. high, were sprayed with Bordeaux mixture 4 times during the summer of 1898. The foliage of these trees was free from fungi and bright in color throughout the summer. All unsprayed trees adjoining were slightly affected with the fungi. The labor of applying the mixture is no greater than in spraying apple trees. The body blight of the chestnut is described. It is thought to be in nature not unlike the sunscald of cherry and other young fruit trees. The advantages of the Japanese and European groups are presented in the form of the parallel. A monograph of varieties is appended.

Report of the horticulturist, P. H. ROLFS (*Florida Sta. Rpt. 1898, pp. 36-54*).—Brief notes are given on peaches, asparagus, broccoli, plums, Brussels sprouts, cauliflower, celery, cucumbers, rhubarb, and water cress, together with a table showing the date of sowing, time ready for market and number of days from seeding to gathering of numerous varieties of beans, peas, Brussels sprouts, sweet corn, cabbage, cauliflower, carrots, cucumbers, collard, garden cress, chicory, cherville, endive, English pea, eggplant, kohlrabi, lettuce, ruta-baga, turnip, tomato, squash, radish, onion, muskmelon, and watermelon.

Simultaneous forcing of carrots and radishes in the same bed, E. LAMBERT (*Rev. Hort., 71 (1899), No. 5, pp. 110, 111*).—A statement of a method which is said to be profitable, together with a list of varieties best adapted for such forcing.

Forcing head lettuce; soils and fertilizers, F. H. HALL and S. A. BEACH (*New York State Sta. Bul. 146, popular ed., pp. 8, pls. 2*).—A popular summary of Bulletin 146 of the station (see p. 957).

Chervil in the sixteenth century, E. ROZE (*Jour. Soc. Nat. Hort. France*, 3. ser., 21 (1899), Jan., pp. 75-79).—Notes on the history and present utilization of this vegetable in France.

Protecting tender trees and shrubs in winter, J. MEEHAN (*Park and Cemetery*, 8 (1898), No. 10, p. 191).—The author states that the winterkilling of many tender evergreens, as *Magnolia grandiflora*, is caused by light and excessive evaporation rather than by low temperatures. Injurious effects resulting from such conditions may be obviated by mulching, covering the foliage, as for instance with leaves, and making screens on the north side of the plant. With deciduous trees and shrubs the screens may be omitted.

Distribution of seeds and plants, E. J. WICKSON (*California Sta. Seed Bul.*, 1898-99, pp. 14).—Owing to the serious drought, the distribution of plants and seeds has been seriously interfered with and the number of applications as well as the amount of material distributed have fallen off at least 50 per cent.

Descriptive notes are given of the various plants and seeds which are offered for distribution. Attention is called to the use of resistant apple roots as a stock where the woolly aphis is particularly troublesome. In order to give them a local trial, roots of selected Northern Spy stock have been imported from Australia and will be distributed for use in root grafting.

Means of preventing depredations by rabbits in orchards and nurseries and methods of treating the injured trees, E. S. ZEVIN (*Deut. Landw. Presse*, 25 (1898), Nos. 102, pp. 1055, 1056; 103, p. 1065).

Canning fruit, W. CRAIG, jr. (*Jour. Agr. and Hort.*, 2 (1899), No. 16, pp. 369, 370).—Brief historical notes and a statement of principles involved, together with the method that the author considers best.

Some good berries, F. H. HALL and W. PADDOCK (*New York State Sta. Bul.* 147, popular ed., pp. 4).—A popular summary of Bulletin 147 of the station (see p. 961).

The Marcon and Cazenave systems of grape training, P. MOUILLEFERT (*Jour. Agr. Prat.*, 63 (1899), No. 8, pp. 286-288, figs. 5).—The former is a modification of the latter; both belong to the French long-pruned cordon system. Neither can be used except with certain varieties on very rich soils.

A method of training the grape in upright cordons by looping, C. GROSDMANGE (*Rev. Hort.*, 71 (1899), No. 5, pp. 105, 106, figs. 2).—A method devised by M. Pécheux. It consists in taking a loop in the cordon and, after pruning, fastening the upper part of it downward at a considerable angle. This method is highly recommended. It is also used on the peach, though with more difficulty.

Green manuring of the vine on the light soils of the center and west of France, G. PAGEOT (*Jour. Agr. Prat.*, 63 (1899), No. 8, pp. 288-290; 9, pp. 311-314).—On very poor light soils chemical fertilizers have not given satisfaction. A method is described for the use of green manuring in vineyards on such lands, with an itemized statement of the expense.

The European and Japanese chestnuts in the eastern United States, G. H. POWELL (*Delaware Sta. Bul.* 42, abridged ed., pp. 16, figs. 7).—This is an abridged edition of Bulletin 42 of the station (see p. 962).

Raising new varieties of carnations from seed (*Florists' Exchange*, 11 (1899), No. 10, p. 254, figs. 6).—Practical directions, dealing mostly with the mechanical details of cross pollination.

Synonyms in chrysanthemums, J. F. FAVARD (*Rev. Hort.*, 71 (1899), No. 3, p. 67).—A list of synonyms established by the Committee on Classification of the National Chrysanthemum Society of England.

The decline of the orchid (*Garden*, 55 (1899), No. 1423, pp. 127, 128).—A consideration of the causes that have led to a decline, which the author assumes in this article has taken place. While specific application of the argument is made only to the orchid, the discussion would apply with equal force to other flowers that have for a time enjoyed a great measure of popular favor but whose popularity is on the wane.

The history of the Pelargonium, S. HIBBERD (*Jour. Hort.*, 51 (1899), No. 2630, p. 153; 2631, p. 172).—A reprint of a lecture delivered before the Royal Horticultural Society in 1880.

FORESTRY.

Progress and effects of forest growing, R. W. FURNAS (*Forester*, 4 (1898), No. 12, pp. 213-218).—The object of this somewhat popular paper is to show briefly what has been done and what may be done in converting the naturally timberless portions of the country into tree-growing regions. It is based upon the author's personal experience during a residence of 43 years in what is now the State of Nebraska. The early attempts at forest planting are described and the effect of tree-planting legislation shown. The author states that from 1854 to 1896, 298,479 acres of land have been planted to forest trees in the State of Nebraska. This includes seedlings, seeds, and cuttings planted in permanent forests, groves, and along highways and streets. Spontaneous indigenous growth is estimated to equal half as much as the area planted. The different methods of planting are discussed; and placing the estimate at the average distance of planting the author states that the area planted, together with the spontaneous increase would give a grand total of 1,065,689,757 trees for the 43 years. To this should be added 15,838,250 fruit trees which have been planted within the State.

The different kinds of forest trees which can be successfully and satisfactorily grown, both when planted and spontaneously growing, are enumerated. The following actual measurements of tree growths of known ages were made by the author and the Hon. J. Sterling Morton a few years since, showing the circumference in inches 2 ft. above ground:

Size of forest trees of known ages grown in Nebraska.

	Age.	Circumference.		Age.	Circumference.
	Years.	Inches.		Years.	Inches.
White elm	15	24 $\frac{1}{2}$	Black walnut	22	48
Do	24	63	Do	16	18
Red elm	24	36	Do	16	15 $\frac{1}{2}$
Catalpa	20	48 $\frac{1}{2}$	White walnut	16	49 $\frac{1}{2}$
Soft maple	18	54 $\frac{1}{2}$	Osage orange	25	26 $\frac{1}{2}$
Do	18	69 $\frac{1}{2}$	Larch	10	24
Sycamore	16	43 $\frac{1}{2}$	White pine	20	36 $\frac{1}{2}$
Pig hickory	24	27 $\frac{1}{2}$	Do	12	29
Shag-bark hickory	24	30	Scotch pine	15	23
Cottonwood	23	78 $\frac{1}{2}$	Do	10	36
Do	11	93	Austrian pine	11	92 $\frac{1}{2}$
Do	25	98	Balsam fir	12	26
Chestnut	14	24 $\frac{1}{2}$	Red cedar	12	26 $\frac{1}{2}$
Box elder	14	25 $\frac{1}{2}$	White cedar	12	22
Do	14	31 $\frac{1}{2}$	Mulberry	18	43
Honey locust	22	40 $\frac{1}{2}$	Do	18	39 $\frac{1}{2}$
Do	22	41 $\frac{1}{2}$	Russian mulberry	6	24
Kentucky coffee tree	14	25 $\frac{1}{2}$	Linden	14	35
Bur oak	22	36 $\frac{1}{2}$	Poplar	4	12
Do	26	43 $\frac{1}{2}$	Silver-leaf poplar	12	67
White oak	22	29	Black locust	24	60 $\frac{1}{2}$
Red oak	22	37 $\frac{1}{2}$	Red willow	20	58
Black oak	22	38 $\frac{1}{2}$	Gray willow	15	26 $\frac{1}{2}$
White ash	22	32 $\frac{1}{2}$	Yellow willow	21	132
Green ash	22	30			

The relative value of different kinds of trees is discussed, the cost of planting, distances, and some of the insect enemies of forest trees are mentioned.

Preserving timber for estate and other purposes, D. F. MACKENZIE (*Trans. Highland and Agr. Soc. Scotland*, 5. ser., 10 (1898), pp. 1-26, figs. 13).—The author describes various kinds of timber and gives in some detail methods for preserving the same. The ingredients chiefly used are vegetable oils and tar mixed together, creosote, copper sulphate, iron sulphate, zinc chlorid, sodium chlorid, mercury bichlorid, calcium chlorid, and other ingredients such as carbolic acid, arsenical acids, lead acetate, and barium sulphurate. The methods described are immersion in a solution of chlorid of zinc, immersion in corrosive sublimate, a solution of copper sulphate applied under pressure, a solution of iron sulphate combined with a solution of barium or calcium injected into the wood; the creosote process and a process called thermo-carbolization. This last process consists of the treatment of wood with carburated steam in order to extract the natural sap and free water and at the same time charge the vessels or pores with a preserving agent. The cost of the different methods is given and the special advantages of each discussed.

Cultivated shade and forest trees, B. C. BUFFUM (*Wyoming Sta. Bul.* 38, pp. 34, pls. 12).—The general forestry conditions of the State are briefly stated and the danger of extinction of native forests, the necessity for their preservation, and the influence of the trees on the growth of plants are pointed out. Suggestions are given for the planting and care of trees, and some experiments which have been carried on by the station are reviewed. It appears that at high elevations sudden frosts in the fall arrest the growth of many trees before they have ripened their wood. On this account some of the slow growing varieties, such as hardwood trees, fail to increase in size above the ground because each season's growth dies back to the original stem or to the top of the ground in the fall or winter. This has occurred year after year with ash, elm, and honey locust and sometimes with the willows where no protection was given them.

Detailed notes are given of the relative value of a number of trees for forest as well as ornamental planting in Wyoming. Arranged in the order of their hardiness, the list of trees which have been tested in the State is as follows: Cottonwood, willow, silver spruce, Douglas spruce, box elder, hardy apples, dwarf cherry, silver maple, cedar, white ash, green ash, locust, elm, Morello cherries, plums, mountain ash, soft maple, black walnut, butternut, birch, mulberry, catalpa.

A number of insect enemies which are liable to be met with are mentioned and remedies suggested for their destruction.

The home nursery in forestry, A. C. FORBES (*Gard. Chron.*, 3. ser., 25 (1899), No. 638, pp. 163, 164).—The advantages of a home nursery are pointed out and suggestions given for its management.

Concerning the American red cedar (*Oesterr. Forst. u. Jagdw. Ztg.*, 17 (1896), No. 8, p. 60).—Notes are given on *Juniperus virginiana*.

The reforestation of white pine lands (*Forester*, 5 (1899), No. 3, pp. 61, 62).—Quotations are given from the Forest Warden of Minnesota on the present condition of the pine forests of the State and notes on the possible income from reforested lands.

Measuring the forest crop, A. K. MŁODZIANSKY (*V. S. Dept. Agr., Division of Forestry Bul.* 20, pp. 71, figs 15).—This bulletin is a brief presentation of the methods by which measurements of felled and standing trees, as well as of whole forests, may be performed, together with a discussion of a method developed by the author for ascertaining the rate of growth of trees and forest crops. This method, it is said, has been tested, and the results obtained recommend it for the rapidity with which a large number of measurements may be coordinated and summarized.

Periodicity in the growth in thickness of trees, J. WIELER (*Tharand. Forst. Jahrb.*, 48 (1898), p. 100; *abs. in Jour. Roy. Micros. Soc.* [London], 1899, No. 1, p. 52).—It is stated that often in closely contiguous spots the growth and thickness of tree trunks is far from uniform. There are in general, both with conifers and dicotyledons, 2 periods of greatest activity, the one about the beginning of June and the other about the middle of July. The latter period of activity is subject to great variations. The period of greatest activity in the development and unfolding of buds does not necessarily agree with the greatest activity of the cambium.

SEEDS—WEEDS.

Experiments on red clover seed, A. N. MCALPINE (*Trans. Highland and Agr. Soc. Scotland*, 5. ser., 10 (1898), pp. 224-234).—The author conducted a series of experiments to ascertain whether there was any connection between the yield of clover and the general appearance; size, weight, name, nationality, and price of seed.

Seven lots of seed were purchased in the open market and their purity and germination determined, after which they were distributed to various growers and grown under numbers, no indications being given the grower as to the origin of the seed. The principal experiment in growing was made at Carbeth, where it was continued for 4 years. In the accompanying table the price per pound, purity, germination, number of seed per pound, yield of hay per plat for 4 years, and order of productiveness is given:

Comparative tests of red clover seed.

	Price per pound.	Purity of seed.	Germination of seed.	Number seed per pound.	Yield of hay per plat. 4 years.	Order of productiveness.
	<i>Cents.</i>	<i>Per cent.</i>	<i>Per cent.</i>		<i>Cwt.</i>	
American	12	98	84	297, 300	70 3	3
Canadian	14	100	92	287, 400	67 5	4
French	15	99	87	272, 600	58.6	6
American (<i>Trifolium medium</i>)	15	100	91	260, 000	75.9	2
New Zealand	19.5	100	92	212, 500	76.1	1
English	24	98	94	216, 300	64.7	5
German	15	99	89	206, 900	42.8	7

Other experiments conducted at different places showed either very slight or no appreciable difference. In one case the yield of the plat seeded with American red clover exceeded that of any of the others. In hardiness, as shown by the last cutting at Carbeth, *Trifolium medium*

ranked first, American red second, Canadian third, the others greatly inferior, and the French nothing.

The general conclusion is drawn that the product depends on the germinating power of the seed used and the number of pure and germinating seed per pound. If these conditions are satisfied the size and appearance of seed will be of little account. As a satisfactory basis for valuation of seed the author states that the purchaser should take into account the percentage of purity, percentage of germination, and number of seeds per pound. The highest priced seed in his experience did not yield the largest crop.

Studies in germination, V. JODIN (*Ann. Agron.*, 21 (1898), No. 8, pp. 382-397).—The author continues to report his investigations on the germination of seed, the present paper treating of the differences between very old and fresh seed in their intramolecular respiration and on the potentiality of seed. Intramolecular respiration was found to diminish as the age of seed increased. Peas 33 years old failed to give off carbon dioxid when in suitable media for germination. A very small quantity was given off from 27-year-old peas and increasing amounts from still newer seed.

Influence of the weight of seed on the yield of cereals, L. GRANDEAU (*Jour. Soc. Agr. Brabant-Hainaut*, 1898, No. 47).

Tobacco seed: its choice; light and heavy seed, TRABUT (*Gouv. Algerie Bot. Service Bul.*, 1898, No. 17, pp. 8, illus.).

On the specific gravity of rice seeds at different stages of ripening, H. ANDO (*Imp. Univ. Col. Agr. [Tokyo] Bul.*, Vol. 3, No. 5, pp. 479-481).—The specific gravity of rice seed was tested at various periods of growth, namely, milk-ripe, green-ripe, yellow-ripe, full-ripe, and dead-ripe. From the tables given it is clearly shown that the specific gravity increases with ripening.

DISEASES OF PLANTS.

On the use of sulphur and sulphate of ammonia as preventives of potato scab in contaminated soils, H. J. WHEELER and G. E. ADAMS (*Rhode Island Sta. Rpt.* 1897, pp. 254-268).—The trials with sulphur which were conducted in 1896 (E. S. R., 8, p. 798) indicated that when thoroughly mixed at the rate of 600 lbs. per acre in the upper 7 or 8 in. of a badly contaminated soil, though checking the diseases somewhat, was practically useless. In 1897 2 series of experiments were made to continue the study.

In the first series seed tubers of the variety New Queen, which were practically free from scab, were planted in pots 26 in. deep and 18 in. in diameter, which were buried in the ground to within 2 in. of their tops. Each pot received as fertilizer air-slaked lime, dried blood, nitrate of soda, muriate of potash, dissolved boneblack, and tankage. In previous years the pots had received barnyard manure alone or with common salt, sodium carbonate, or oxalic acid. Sulphur and corrosive sublimate were compared as fungicides. Part of the tubers were treated with 1:1,000 corrosive sublimate solution for 1½ hours; others

were moistened and rolled in sulphur at the rate of 300 lbs. per acre, the sulphur not adhering to the tubers being dusted over them before covering by the soil; and other tubers received no treatment. The results obtained showed that the sulphur treatment was slightly more efficient than corrosive sublimate, and also that the disease germs were present in great quantities in the soil, as otherwise the corrosive sublimate treatment would have reduced the amount of scab as compared with no treatment.

In the second series of experiments the same pots and soil were used as in previous experiments, which had been treated with lime, wood ashes, calcium chlorid, sulphate, carbonate, oxalate, or acetate. The seed tubers were washed before attempting to examine them for scab. All the tubers were treated with 1:1,000 corrosive sublimate solution for 1½ hours before planting. In addition, a part of the tubers were treated with sulphur in the same manner as in the first experiments. The efficiency of the acid soil and calcium sulphate and chlorid in preventing the development of scab was shown, not a trace of scab being found where either of the calcium compounds were applied. The poisonous action of these substances on the crop was quite markedly indicated, as in previous years' experiments. Comparing the sulphur and corrosive sublimate treatment for the prevention of scab, it was found that there was a reduction of about 21 per cent in the number of badly scabbed tubers where sulphur was used.

In consideration of the cost of sulphur when applied in large quantities, and owing to the fact that it has little or no manurial action, the results are compared with the favorable results previously obtained with sulphate of ammonia, and further experiments in this line are promised.

The authors summarize their results as follows:

“The results of 1897 fully confirm those of previous years as to the tendency of carbonate of lime, and all combinations of lime which are changed into that form within the soil, to promote in a striking degree the development of the potato scab.

“On a badly contaminated soil the use of sulphur for 2 consecutive years, in quantities amounting in all to 900 lbs. per acre, reduced the amount of scab in a decided degree.

“Owing to the cost of sulphur, and the improbability of its being of more than slight, if any, indirect manurial value, it appears possible that the employment of sulphate of ammonia, which is at the same time a valuable source of nitrogen, might prove more economical than sulphur in reducing the tendency to scab on soils already contaminated with the scab fungus. The results thus far secured indicate that if it were employed in connection with kainit, sulphate, or muriate of potash, soils would be rapidly improved in this particular.

“Owing to the fact that soils naturally favorable to the development of the potato scab are also favorable to nitrification, the fullest manurial action of the sulphate of ammonia should be obtained.”

The asparagus rust, L. F. KINNEY (*Rhode Island Sta. Rpt. 1897, pp. 317-321*).—During the summer of 1897 the asparagus rust (*Puccinia asparagi*) made its appearance in various Rhode Island market gardens.

Prior to this time the disease had not been reported by asparagus growers in the State, but a thorough investigation showed it rather generally spread. The effect of the disease upon the plants is shown in their exhausted vitality. The mowing and burning of the stalks was thought a possible means for the prevention of the spread of this disease, but its wide distribution showed that nothing would be gained by such treatment. All efforts to control asparagus rust have been only partially successful. The difference in the amount of rust found on different varieties, the author thinks, may not be wholly due to varietal peculiarities, but from the limited data accessible there appear to be differences in resistance. Shallow plowing of the beds after the stalks have been cut has been tried, and it is thought possible in this way that the spores of the fungus which are lying on the surface may be covered and destroyed. The aggregate value of asparagus beds in the 2 centers referred to in this report is said to be \$200,000, and should this disease continue its course for a few years the greater part of the capital would be lost.

Studies on *Puccinia ribis* of red currants, J. ERIKSSON (*Rev. Gén. Bot.*, 10 (1898), No. 120, pp. 497-506, pl. 1).—As a result of his experiments the author concludes that *Puccinia ribis* is a true micro-puccinia with only 1 generation of spores. These are telentospores, which germinate the spring after their formation. In the fungus it is possible to distinguish a special form to which the author gives the name *rubri*, which attacks the red currant and also a variety of the white, but not the black currant, nor in all probability does it attack the gooseberry. The appearance of the disease occurs in the spring after hibernation of the spores, and the period required for their germination is from 29 to 39 days. As preventive measures against the destructive effect of this fungus, the author recommends the collecting together and burning in the fall of the year all leaves and diseased fruits which fall from the bushes. In the spring all bushes which are liable to attacks of this fungus should be thoroughly sprayed about the time their buds begin to swell, 2 applications of Bordeaux mixture being given during the season. Not only should the bushes be sprayed, but the ground underneath them.

Contribution to the knowledge of *Coleosporium* and the leaf rust of pines, G. WAGNER (*Ztschr. Pflanzenkrankh.*, 8 (1898), No. 5, pp. 257-262).—The author reviews a number of experiments and statements on the relation existing between the alternate host plants of a number of species of *Peridermium* and *Coleosporium*. He briefly reviews his own experiments in which a number of plants were inoculated with the æcidiospores from *Pinus sylvestris* and *P. montana*. It was found that in nearly every case the æcidiospores would infect *Melampyrum pratense* and *Euphrasia officinalis*, but not *Campanula rotundifolia*, *C. trachelium*, *Phyteuma officinalis*, and *Tussilago farfara*.

In a subsequent note in the same journal (No. 6, p. 345) the author

claims to have infected pine needles with spores from *Coleosporium campanula micrantha*, the spermagonia appearing in October.

Inoculations of pine needles made in September with spores of *C. sonchi-arcensis* from *Sonchus asper*, and *C. tussilaginis* from *Tussilago farfara* resulted in the appearance of spermagonia in November.

The leaf-spot disease of walnuts H. BOLTSCHAUSER (*Ztschr. Pflanzkrankh.*, 8, (1898), No. 5, p. 263).—The author reports the appearance in Thurgau during July of the past year of a disease of walnut leaves. The spots were very numerous, round, and dry, the inner portion brownish gray, and the outer part darker, more or less arranged in zones. The spots were of various sizes, ranging from 1 mm. to 1 cm. in diameter and occurred on both sides of the leaves. The dried leaf substance finally falls from the leaves. The perithecia which are found on the upper side of the leaf are globular, more or less sunken, about 0.08 mm. in diameter. The spores are oblong, 2-celled, and often constricted in the middle. They are from 0.01 to 0.013 mm. in length and from 0.004 to 0.005 mm. in diameter. The fungus, which appears to have been undescribed, has been given the name *Ascochyta juglandis*.

Notes on the Michigan disease known as "little peach," E. F. SMITH (*Reprint from Fenville Herald, 1898, Oct. 15, pp. 12*).—In an address before the Saugatuck and Ganges Pomological Society the author describes this little-known disease which threatens to become of great importance to the peach growers of that State. The symptoms of the disease are the dwarfing of the fruit, retarded ripening of fruit, absence of any red spotting of skin or flesh, the dwarfing or yellowing of the foliage from the start, and the absence of sprouting winter buds. The affected peaches are badly dwarfed, usually one-half or less the size of ripe healthy peaches of the same variety. The color of the skin and flesh is normal. The pits are small but hard and well developed. The leaves are much smaller than normal, perhaps on an average only about half as large. They are thicker, of a sickly, yellowish, reddish, or brownish green color. The diseased leaves examined were found free from mildew, fungus, or insect depredations. Unlike the rosette and yellows of the peach this disease often appears on all parts of the tree, although sometimes it appears first on one or more limbs, spreading to the remainder of the tree. The main root and all other larger branches appear sound in bark and wood, but the ultimate rootlets were found badly diseased in every specimen examined, fully nine-tenths of the rootlets being found dead and shriveled or brown and dying. Trees attacked by this disease are said to die the second or third year. This disease has been attributed to various causes, several of which are discussed. The author states that in his opinion the disease is due to shutting off of the water supply to the tree, but whether this is brought about by some parasite or by drought combined with overbearing and unsatisfactory condition of soil can not as yet be determined.

Report of the biologist, P. H. ROLFS (*Florida Sta. Rpt.* 1898, pp. 27-36).—The work in botany for the year is briefly reviewed and notes given on a number of important plant diseases. The fungus tomato blight is briefly discussed, a more extended description and discussion having been given in Bulletin 21 of the station (E. S. R., 5, p. 790). The bacterial tomato blight and tomato rust are also described. Notes are given on the fungus disease of the San José scale, a detailed account having been previously published in Bulletin 11 of the station (E. S. R., 9, 1068). Celery blight, due to *Cercospora apii*, and the pear blight or twig blight are described, and preventive measures suggested.

Diseases of cultivated plants in Cyprus, P. G. GENNADIUS (*Rpt. Agr. Cyprus*, III, p. 51; *abs. in Ztschr. Pflanzenkrank.*, 8 (1898), No. 5, pp. 281-283).—Notes are given on diseases of grapes, citrus fruits, olives, apple trees, and cereals. A brief report is given on the destruction of Orobanche and Euphorbias. The first plant, it is said, may be destroyed by applications of potash and phosphate fertilizers, also 5 per cent solutions of copper sulphate will destroy Orobanche seeds. The Euphorbias, it is said, may be destroyed with carbon bisulphid, or with petroleum mixed in fertilizers.

Diseases of sugar cane in the Antilles, G. SAUSSINE (*Bul. Agr. Martinique*, 1898, No. 2, pp. 41-53).—Notes are given on *Alectra brasiliensis*, a saprophytic phanero-gam, 2 cryptogams (*Trichosphaera sacchari* and *Colletotrichum falcatum*), and several diseases of unknown origin.

Fungus diseases of the grapevine, ALLEN, BLUNNO, FROGGATT, and GUTHRIE (*Agr. Gaz. New South Wales*, 10 (1899), No. 1, pp. 26-31).—Notes are given on a number of diseases of the grape, with suggestions for their prevention.

Black rot of grapes and its treatment, G. D'ÚTRA (*Bol. Inst. Agron. São Paulo*, 9 (1898), No. 6, pp. 268-271).

The treatment of pourridie L. ROUGIER (*Prog. Agr. et Vit. (ed. L'est)*, 20 (1899), No. 11, pp. 327-333).—Carbon bisulphid is said to be the most efficient means for preventing the destruction of grapevines by *Dematophora necatrix*.

On the use of carbon bisulphid against Dematophora necatrix, J. DUFOUR (*Chron. Agr. Cant. Vaud*, 12 (1899), No. 4, pp. 87-90).—Notes the very successful use of this fungicide against this pest.

Monilia variabilis, P. LINDNER (*Wehnschr. Brau.*, 15 (1898), No. 16; *abs. in Bot. Centbl.*, 77 (1899), No. 2, pp. 67, 68).—A variable new species is described which was found growing upon white bread that had been moistened with beer yeast.

The chrysanthemum rust, L. WITTMARCK (*Gartenflora*, 47 (1898), No. 23, pp. 625, 626, fig. 1).—Notes are given on *Puccinia hierocii*.

Tea blights, G. A. MASSEE (*Kew Misc. Bul.* 138, pp. 105-122, pl. 1).—The author describes the attack on tea of *Pestalozzia quepini*, *Exobasidium verans*, and *Stilbum nanum*. The first species is also parasitic on rhododendron, citrus, magnolia, etc.

Mildew of hops, L. MANGIN (*Jour. Agr. Prat.*, 1899, I, No. 10, pp. 345-347, fig. 1).—Notes are given on *Spherotheca castagnei*.

A pestalozzia disease of lupines, F. WAGNER and P. SORAUER (*Ztschr. Pflanzenkrank.*, 8 (1898), No. 5, pp. 266-271, pl. 1).—The authors describe a very destructive disease of lupines, which is said to be caused by *Pestalozzia lupinii*, n. sp. Different species of lupines seem to vary in degree of susceptibility to the disease, *Lupinus crulkshanksii* and *L. mutabilis* being quite susceptible, while *L. albus* and *L. luteus* are less so. In cultivating these plants to avoid the disease care should be taken in the selection of varieties, and the soil should not be allowed to become too wet.

The mycoecidia of Ræstelia, L. GENEAU DE LAMARLIÈRE (*Rev. Gén. Bot.*, 10 (1898), No. 114, pp. 225-237; 115, pp. 273-288, pls. 2, figs. 5).

An undescribed disease of peonies and lily of the valley, J. RITZEMA-BOS (*Ztschr. Pflanzenkrank.*, 8 (1898), No. 5, pp. 263-266).—The author describes diseases of the peony and lily of the valley which are said to be caused by *Botrytis peonia*. On both plants it has proved quite destructive. Experiments were made on *Convallaria*

leaves which were sprayed with Bordeaux mixture. In one case the leaves were severely injured by the treatment, while in the other case there was little evidence of checking the spread of the disease.

A bacterial disease of *Juniperus phœnicea*, F. CAVARA (*Bul. Soc. Bot. Ital.*, 1898).

Wet rot in potato, C. WEHMER (*Ber. Dent. Bot. Gesell.*, 16 (1898), pp. 172-177, figs. 2; *abs. in Jour. Roy. Micros. Soc.* [London], 1899, No. 1, p. 69) —The opinion is expressed that the wet rot of the potato is not primarily a bacterial disease, but is due to certain conditions of environment. The author's experiments show that potatoes placed in moist positions, although exposed to aerial and contact infection, remain free from wet rot if they are left uncovered; on the other hand, if covered, the tubers will in a few days be affected with wet rot. When the environmental conditions are suitable, the bacteria are active, and though it is possible that many may be able to produce decomposition, there are 2 species most frequently met with, namely, *Bacillus* sp. and *Amylobacter naticula*.

Recent observations on *Pseudocommis*, E. ROZE (*Bul. Soc. Mycol. France*, 15 (1899), No. 1, pp. 37-43).—Experiments with this myxomycete on beans are briefly reported.

Underground galls of beets and crucifers and their causes, VON DOBENECK (*Pract. Bl. Pflanzenschutz*, 1 (1898), pp. 61, 62).

Nematodes and means for combating them, C. SCHREIBER (*Agronome*, 1898, Nos. 47, 48).

ENTOMOLOGY.

Some injurious insects, A. L. QUAINANCE (*Florida Sta. Rpt.* 1898, pp. 56-72, pls. 4).—Notes are given on a number of insects which have proved more or less destructive to certain economic plants. The sweet potato prodenia (*Prodenia commelinae*), which has heretofore been considered of little economic importance is described. During the fall of 1896 and the summer of 1898, the larvæ caused considerable destruction by feeding on tomato and Irish potato leaves. In a number of places the insect has been observed feeding on sweet potato leaves and has caused considerable damage to the crop throughout the regions infested. After the foliage has been eaten the larvæ have been observed to migrate and attack various plants, such as crab grass, wild coffee plant, partridge pea, tomato, okra, and tobacco. But little data are given as to the life history of the insect. For its prevention the use of Paris green at the rate of 1 oz. to 10 gal. of water, to which 1 oz. of quicklime previously mixed should be added, is recommended.

A number of scale insects are described, among them the snowy chionaspis (*Chionaspis minor*), which has been abundant on the China tree (*Melia azederach*). It has also been reported as feeding on palms, cotton, capsicum, hibiscus, and grapevines. The appearance of the scale is briefly described, and it is stated that thorough winter spraying with strong whale-oil soap or a kerosene-and-water mixture might prove efficient in destroying this pest.

The fig scale (*Asterolecanium pustulans*) is known in the east coast region of Florida, where it occurs on the fig, mulberry, and oleander. The scale is somewhat circular in outline, slightly convex, and of a yellowish color. Under a hand lens the scale is seen to be surrounded

by a delicate fringe of pink color. No experiments are known with insecticides, and it is thought advisable to destroy infested plants by digging them up and burning them.

The cassava scale (*Mytilaspis alba*) made its appearance in Florida in March, 1898, on cassava canes which had been imported from Nassau. A considerable quantity of the infested canes were destroyed, and the author visited the fields in which the remaining canes had been planted, but after a careful investigation was unable to find any trace of insects. While it is believed that this threatened pest has been exterminated, the immediate burning of cassava or other plants upon which it is discovered is recommended.

The rust-red flour beetle (*Tribolium ferrugineum*) has proved a serious household and museum pest in Florida. Flour, corn meal, and similar products become badly infested if left exposed. In museums the pest is particularly severe, especially on dried insects. Its methods of attack and injury are described and brief notes given on the life history, from which it appears that the life cycle is completed in about 30 days. The egg state continues for 12 days, the larval 14 days, the pupa state about 5 days. The life of an adult in captivity is from 25 to 30 days. The different stages in the life history of this insect are described. Where it is possible the use of carbon bisulphid is recommended as a treatment.

Notes are given of the chinch bug, which has occurred in various places in Florida, but on account of the amount of wet weather which occurs in the State, it is thought probable that it will never prove seriously destructive in the State.

The rubus white fly (*Aleurodes ruborum*) was first noticed in November, 1898, infesting several of the varieties of *Rubus trivialis*. The presence of these scales in such great numbers would necessarily be a serious drain upon the plant, but the insects have been closely observed since their discovery and there seems to be no occasion for regarding it as of very great economic importance. This scale is probably a native of Florida and has been taken in several widely separated localities on both *Rubus trivialis* and *R. cuneifolius*. A number of hymenopterous parasites have been bred from the pupæ, and it is stated that about 65 per cent of the pupæ are destroyed by parasites.

The ramie-leaf roller (*Pyrausta theseusalis*) has been abundant on the leaves of ramie grown at the station for the past 2 years. Fully 50 per cent of the leaves were rolled up from one side forming a hollow tube $\frac{1}{2}$ inch in diameter. Within these tubes the larvæ feed, eating along the rolled up and covered margin, or sometimes eating the distal end of the tube. These insects have not been observed earlier than July and seem to be most abundant about the middle of September. Specimens of young larvæ placed in breeding cages grew to adult larvæ in about 20 days, pupated within the rolled up leaves, and developed into adults in 23 days. Attempts to secure eggs from moths bred in confinement were fruitless, but making due allowance for the

egg state, the life cycle is probably not shorter than 50 days. A description is given of the different stages of the insect, and as a preventive treatment the author states that probably the best means would be to pick off and burn the rolled up leaves as soon as observed. The use of Paris green or some other arsenite might be of value, but from the feeding habit of the insect many would doubtless escape poisoning.

The report concludes with descriptions and notes on *Pyrameis cardui*, the larvæ of which has been observed for the past 2 years feeding upon prickly comfrey grown in the station grounds.

A serious attack on the apple fruit by *Argyresthia conjugella* in Europe, E. REUTER (*Canad. Ent.*, 31 (1899), No. 1, pp. 12-14).—The presence of this new apple pest in British Columbia has been mentioned in the report of the Canadian Experimental Farms for 1896 (E. S. R., 10, p. 856), in which it is stated that the injuries done closely resemble those caused by the apple maggot (*Trypeta pomonella*). The caterpillars tunnel the pulp of the fruit, leaving brown colored channels, with rather large chambers here and there; this attack thus being easily distinguishable from that of the common codling worm.

According to the author, during the summer of 1898, there was an unexpected and violent attack of this insect on the apple in Finland. In Finland this insect ordinarily feeds on the fruit of the mountain ash and sometimes on that of the bird cherry, but in the summer of 1898 the fruit of both of these failed almost entirely and the insect, not finding its ordinary food, swarmed in immense numbers to the apple trees.

On the relations of a species of ant (*Lasius americanus*) to the peach-root louse, F. M. WEBSTER (*Canad. Ent.*, 31 (1899), No. 1, pp. 15, 16).—The author has had occasion to study the root louse on the roots of young peach trees and has been impressed with the attention given them by ants. Attention has previously been called to the relation existing between ants and peach-root louse by E. F. Smith,¹ who stated as probable that the ants bring the plant lice from below ground in the spring and place them upon the twigs, thus indirectly causing their diffusion in the orchards.

In the investigations reported the author states that he has not only been able to observe the attention of the ant in caring for the aphid on the roots, but has also found them transporting them about on the twigs, and he has no doubt that they are also transported from twig to root and *vice versa*. Below ground the aphid is said to usually cluster upon the tender roots or rootlets with ants in constant attendance. Where there was a lack of rootlets the bases of some of the roots and also the crown had patches of bark removed, and the wounds had every appearance of having been caused by gnawing away the bark. On further examination it was found that where these wounds had begun to heal over, the wounds were closely packed with the root lice attended by ants. It appears that the aphid can subsist on this tender growth

¹Entomologica Americana 6, p. 101.

of over-healing bark as well as though they were colonized on the tender rootlets. Where the wounds on the peach roots were infested by the aphid all bits of gum and detached bark had seemingly been removed, thus giving a clear area for the work of the aphid; and here as elsewhere the ants were found carefully looking after them. The conclusion reached is that the ants intentionally gnaw the bark on the roots where there is a lack of rootlets for the required feeding in order to furnish a supply of food for the aphid.

Second report on the San José scale, H. P. GOULD (*New York Cornell Sta. Bul. 155, pp. 159-171, figs. 3*).—The observations recorded in this bulletin are in continuation of those previously given (E. S. R., 10, p. 468). The author is inclined to believe that by the use of mechanical mixtures of kerosene and water it is possible to kill the scale and not injure the foliage of the plants. His experiments reported in the previous bulletin were repeated during 1898, and a large number of small pear trees badly infested with the San José scale were treated with solutions and mixtures of whale-oil soap, pure kerosene and kerosene diluted with various amounts of water, quassine, and West's insecticide. The effects of these different insecticides upon the foliage of the trees is given and their efficiency as insecticides compared. The best results were obtained with the kerosene.

The author states that the practicability of spraying for the destruction of the San José scale will depend largely upon conditions. In the case of fruit trees or ornamentals permanently set which have not become weakened by attacks of the insect it will be entirely feasible to protect the trees from further injury by spraying them with kerosene, but spraying can not be recommended for nursery stock. For the latter fumigation with potassium cyanid is recommended. The most satisfactory time for spraying is during the active stage of the scale in the summer and early fall.

The effect of kerosene on peach and apple trees was investigated to some extent. It is stated that pure kerosene will seriously injure peach trees even when they are in a perfectly dormant condition. A 20 per cent mixture can probably be safely used on the peach at any time, but stronger mixtures are to be avoided. Apple trees do not appear as susceptible to injury by kerosene as peach trees, and upon apple trees a mixture containing 50 per cent or less may be used with safety. Kerosene is especially likely to cause injury if applied on other than a bright sunny day. In the author's experiments a 20 per cent solution was found harmless to plants and destructive to all insects.

Diseases of sugar cane in the Antilles, G. SAUSSINE (*Bul. Agr. Martinique, 1898, No. 1, pp. 23-35*).—Notes are given on the following insects: *Diatraea saccharalis*, *Nyleborus perforans*, *Sphenophorus sacchari*, scale insects, plant lice, etc.

Contributions to the knowledge of Coccidæ, T. D. A. COCKERELL and P. J. PARROTT (*Industrialist, 25 (1899), No. 4, pp. 227-337*).

A new enemy of wheat, F. NOACK (*Bol. Inst. Agron. São Paulo, 9 (1898), No. 6, pp. 261, 262*).—The larvae of *Eolus pyroblaptus* are said to be very injurious to wheat.

The flying mechanism of insects, C. JANET (*Compt. Rend. Acad. Sci. Paris*, 128 (1899), No. 4, pp. 249-253).

On the head formation of Hymenoptera at the time of their passing into the nymphal stage, L. G. SEURAT (*Compt. Rend. Acad. Sci. Paris*, 128, 1899, No. 1, pp. 55, 56).

FOODS—ANIMAL PRODUCTION.

On the cleavage products of casein in pancreatic digestion, U. BIFFI (*Arch. Path. Anat. u. Physiol. [Virchow]*, 152 (1898), No. 1, pp. 130-157).—A number of experiments are reported. The principal conclusions follow: Under favorable conditions casein is completely digested. About 4 per cent of the total amount of casein is converted into tyrosin. The final cleavage product of casein (casein antipeptone) has the following percentage composition: C 49.7, H 7.2, N 16.3 (S 1.3), O 25.2. In properties and reaction it is like fibrin-antipeptone. The casein albumoses may be divided into 2 groups, primary and secondary, and agree in their reaction with those from fibrin. Casein-phosphorus occurs in the products of digestion in 2 forms, one may be precipitated with magnesium mixture and the other not. The phosphoric acid compound increases with the length of the period of digestion and the amount of ferment present, while the other phosphorus compound is diminished. Further, the organic phosphorus can be converted into the inorganic compound by the action of dilute alkali solutions and by boiling with barium carbonate in the same way as the phosphorus compounds derived from casein by digestion with pepsin and hydrochloric acid.

Dietary studies in Chicago, reported by W. O. ATWATER and A. P. BRYANT (*U. S. Dept. Agr., Office of Experiment Stations Bul. 55*, pp. 76).—A number of investigations were conducted among families of foreign birth or origin in the thickly congested West Side of Chicago. A number of samples of food were analyzed in connection with the study. In general the usual methods were followed. In some cases the statistics were prepared by the families themselves and the results thus obtained are regarded as not entirely reliable. The average results follow:

Average results of dietary studies—cost and amounts of nutrients eaten per man per day

	Cost.	Protein.	Fat.	Carbohydrates.	Fuel value.
	<i>Cents.</i>	<i>Grams.</i>	<i>Grams.</i>	<i>Grams.</i>	<i>Calories.</i>
Italians, average of 4	15.8	103	111	391	3,060
French Canadians, average of 5	22.1	118	158	345	3,365
Orthodox Russian Jews, average of 10 <i>a</i>	18.4	121	87	410	2,985
Orthodox Russian Jews, average of 4 <i>b</i>	19.0	120	101	406	3,095
Unorthodox Russian Jews, average of 6 <i>a</i>	22.0	153	105	430	3,365
Bohemians, average of 8 <i>b</i>	11.5	115	103	360	2,885
Bohemians, average of 25 <i>a</i>	19.7	143	135	424	3,580
American professional men, average of 3	29.1	104	121	429	3,310

a This average includes both those studies in which the statistics were kept by the families themselves and those in which the statistics were kept by those in charge of the investigations. The figures are not to be considered as entirely reliable.

b This average includes only the studies in which the foods were weighed by those conducting the studies.

The results are discussed in detail and compared with the results of similar investigations in New York and Pittsburg (E. S. R., 9, pp. 1074, 1075).

Foods rich in protein. The advantage of a guaranteed composition, E. B. VOORHEES (*New Jersey Stat. Bul.* 131, pp. 11).—The composition and adulteration of feeding stuffs is discussed. To determine whether the cotton-seed meal sold in the State was adulterated, 17 samples obtained from 11 different counties were examined. Of these 2 samples were undecorticated products. Samples of linseed meal, gluten meals, and other gluten feeds were also analyzed. The maximum, minimum, and average percentage of protein and fat in the samples is reported, and the results of similar work in Maine and Massachusetts are quoted. The advantage of a guaranteed composition of feeding stuffs is pointed out. The cost of protein in the feeding stuffs is discussed:

"A comparison of the composition of these feeds with their average selling prices during the past year shows that the gluten meals, at an average cost per ton of \$18.75, furnish the protein at a less cost than any of the others, while cotton-seed meal, at an average cost of \$24 per ton, is next in order, with gluten feeds with an average cost of \$15.70 third in order, and linseed meal fourth at an average cost per ton of \$28.85. That is, from the standpoint of cheapness of protein alone this is the order that they would take. Other points, however, should be considered, as, namely, their general adaptability and their content of mineral constituents, if these are taken into account as they should be in well-managed dairies, the order of cheapness would be cotton-seed meal first, linseed meal second, gluten meal third, and gluten feed fourth."

The chemical life history of lucern, II, J. A. WIDTSOE and J. STEWART (*Utah Sta. Bul.* 58, pp. 90).—This bulletin, which forms part of an extended study of alfalfa (E. S. R., 9, p. 164), treats of the action of various solvents upon alfalfa, the carbohydrates and nitrogenous constituents of alfalfa, and the digestibility of alfalfa cut at different periods of growth. Other features of the chemical composition of alfalfa are discussed, as well as the proper time to cut this crop for hay.

The action of various solvents on alfalfa (pp. 8-26).—A detailed study was made of the material obtained by the successive action of ether, alcohol, water, dilute hydrochloric acid and sodium hydrate solution upon alfalfa. From 2 to 3 gm. each of different parts of 3 successive crops of alfalfa was extracted with anhydrous ether, with the following results:

Ether extract and dry matter in alfalfa.

	Ether extract in—			Highest yield of dry matter per acre.
	Whole plant.	Leaves.	Stalks.	
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Pounds.</i>
First crop	2.79	4.62	1.52	6,209
Second crop	2.18	3.82	1.08	3,878
Third crop	1.98	3.22	1.05	2,305

The ether extract of plants consists mainly of fat and chlorophyll. In alfalfa chlorophyll very largely predominates.

"It may be more than mere coincidence that the average relative amount of chlorophyll in the leaves varies with the total dry matter produced. No such constant variation exists in the stalks or whole plant. A comparison of the total amounts of chlorophyll in the plant and its parts does not show any definite relations to the dry matter produced; it appears that the percentage, or relative force, maintained throughout the growing period, determines the amount of dry matter a crop can produce. If this relation should be proved to hold in all cases, the maximum yield of dry matter would be known when the average amount of chlorophyll in the leaves had been determined."

The residues from the ether extraction were treated successively with 95 per cent alcohol for 2 hours, and with water for 24 hours, with frequent agitation. The results follow:

Alcohol and water extracts of alfafa.

	First crop.			Second crop.		Third crop.
	Early period.	Flower- ing period.	Late period.	Flower- ing period.	Late period.	
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Alcohol extract:						
Whole plant	16.02	12.04	7.43	9.91	9.26	13.80
Leaves	14.98	13.83	13.07	12.87	13.72	16.59
Stalks	18.48	10.94	5.99	7.68	6.70	10.80
Water extract:						
Whole plant	21.93	17.64	11.34	18.45	15.61	17.66
Leaves	23.44	26.17	21.15	29.07	29.17	23.32
Stalks	19.42	12.36	8.43	10.43	7.90	11.38

The alcohol extract, according to the authors, consists of resins not dissolved by ether, tannins and their derivatives if present in the plant, alkaloids, glucosids, some proteid bodies, amido compounds and glucoses, and saccharoses if present.

Water would extract from the residue from the extraction by alcohol, "in addition to a number of rare substances, the soluble carbohydrates, such as dextrin and other mucilaginous bodies, the soluble albuminoids and the legumins, some amids insoluble in alcohol, and most of the organic and inorganic acids that may be present."

The bearing of this matter on the concentration of plant juice is discussed in some detail.

The residues from the above extractions were treated with 2 per cent hydrochloric acid under a reflux condenser for 1 hour, and then with 1 $\frac{1}{4}$ per cent sodium hydrate at boiling for $\frac{1}{2}$ hour. The residue from this last extraction was dried, weighed, and incinerated, the loss in incinerating being taken as fiber. The alkali extract was determined by

subtracting from 100 the sum of the ether, alcohol, water, and acid extracts and the fiber. The acid and alkali extracts follow:

The hydrochloric acid and alkali extracts of alfalfa.

	First crop.			Second crop.		Third crop.
	Early period.	Flowering period.	Late period.	Flowering period.	Late period.	
Acid extract:	<i>Percent.</i>	<i>Percent.</i>	<i>Percent.</i>	<i>Percent.</i>	<i>Percent.</i>	<i>Percent.</i>
Whole plant	24.92	18.59	13.65	15.96	15.90	18.34
Leaves	26.62	21.96	20.95	21.07	20.94	22.14
Stalks	21.81	15.77	11.25	12.01	13.07	13.33
Alkali extract:						
Whole plant	16.53	16.18	19.01	17.51	17.58	17.62
Leaves	16.95	17.14	23.43	19.45	19.55	20.17
Stalks	15.77	15.62	18.27	16.12	16.59	13.67

Dilute hydrochloric acid would remove from the residue of material extracted with water, starch and allied bodies and the hemicelluloses, gluten and related substances, amines, and inorganic salts. Most of these substances have a very high food value.

"Next to the crude fiber, the alkali extract is the most resistant portion of the plant. It is made up chiefly of the insoluble nitrogenous bodies of the plant, together with small quantities of carbohydrates, organic acids, and other substances. . . .

"All the errors made in the preceding determinations fall upon the alkali extract. In spite of this, duplicate determinations agree fairly well, and the results may be accepted as indicative of the truth. . . .

"The foregoing facts teach much of interest and importance concerning the conditions of solubility of the alfalfa plant at its various stages of growth. We may divide the constituents of a plant into 3 groups according to the solubility (leaving out of consideration the fat): (1) Those easily soluble (in alcohol and water); (2) those difficultly soluble (in dilute acids), and (3) those insoluble, or soluble only in alkalis (fiber, and alkali-soluble). . . .

"Considering the whole plant, during the early period more than one-third is easily soluble, about one-third insoluble, and nearly one-quarter soluble with difficulty. During the flowering period the easily soluble materials decrease to less than one-third, the insoluble increase to nearly one-half, and the difficultly soluble fall to less than one-fifth. During the late period the easily soluble portion becomes less than one-fifth, the insoluble about two-thirds, and the difficultly soluble less than one-eighth.

"The easily and difficultly soluble portions of the plant may be considered almost wholly digestible, while the insoluble portion is but slightly attacked by the digestive juices. The percentage of insoluble and alkali-soluble material during the flowering period is very nearly the same as the indigestible percentage as determined by experiments with animals. A part of the alkali-soluble portion, and of the crude fiber is, of course, digested; and some of the materials of the soluble materials are passed through the body without being digested. The decreasing solubility of the plant with age is due almost wholly to the rapid accumulation of crude fiber. It is quite certain that much of the soluble material becomes so entangled in the fiber as to be practically indigestible. During the cutting periods for alfalfa it may be said that about one-half of the plant is insoluble.

"The leaves do not change very much. They are 10 per cent more insoluble when old than they were when young. During the flowering period the leaves are as good as a cattle food as at any other time.

"The stalks are not much more insoluble than the leaves while the plant is young, but with increasing age they become insoluble very fast. During the flowering periods there is nearly 60 per cent of insoluble matter, and during the late periods more than 70 per cent. This, of course, makes the stalks very indigestible.

The carbohydrates of alfalfa (pp. 27-38).—Following the method proposed by Stone (E. S. R., 8, p. 664) the authors studied the carbohydrates in the different crops and cuttings of alfalfa. In determining starch by malt extract, however, it was found that "duplicate determinations were very discordant. . . . No matter how carefully the work was done, the results were never quite trustworthy. . . . A few preliminary tests indicated active unorganized ferments in the alfalfa after the half hour in boiling water. This part of the research, which promised interesting results, we could not continue." The method adopted by the authors was boiling with hydrochloric acid, allowance being made for the pentosans.

"The carbohydrates of alfalfa, with the exception of the fiber, are, as far as their quantity is concerned, of little importance. The general notion that every fodder plant is made up largely of sugar and starch is far from correct in the case of alfalfa. However, there can be no doubt that the carbohydrates are very important as bodies that stand intermediate between the first products of the plant's constructive activity and the compounds finally deposited within the plant.

"It is interesting to note the intimate connection between the alcohol and water-soluble carbohydrates; if one decreases the other increases, and *vice versa*. It seems as if it matters little whether sugar or dextrin be present, as either one meets the condition of solubility. A similar relation holds, in a less degree, between the starch and the pentosans. The lower sugars mark only the transformation of some body into another, within the plant, and are not characteristic ingredients."

The nitrogenous constituents of alfalfa (pp. 39-54).—The total proteid and the different nitrogenous materials in alfalfa of different crops and cuttings were studied in detail. The determination of the total protein showed that—

"The formation of protein in the whole plant does not keep pace with the increase in dry matter, but that as soon as the crop is in early bloom the proportion begins to decrease. Comparing the leaves and the stalks we see that five-sixths of the total protein was found in the leaves; that at budding time nearly nine-sixteenths, or more than half, was in the leaves; and that eight-thirteenths, or more than one-half was found in the leaves at the first period of full flower."

The determination of the relative amount of albuminoid and non-albuminoid nitrogen showed that—

"The plant and its parts show an absolute gain of albuminoids up to the time when the crop is in full bloom. At that time material is drawn from the leaves and stalks into the roots, and the crop above ground loses some of its albuminoids. The stalks are the last to lose their albuminoids, as would be expected from the fact that the substances taken from the leaves must pass through the stem to reach the root, and the stem is thus made, temporarily, richer. The nonalbuminoids are unfinished albuminoids. It is therefore natural to find the greatest absolute and relative quantities in the young plant, when growth is active. From the time of budding there is a rapid conversion of raw materials into finished products, and during that period, therefore, the nonalbuminoids are almost entirely converted into albuminoids. The leaves, which are more or less active to the death of the

crop, contain (to the end of the season) a small proportion of nonalbuminoids, but not enough to keep an excess in the stalks, which, as a consequence, lose nearly all their nonalbuminoids after the flowering period."

Nonalbuminoid nitrogenous materials are easily soluble in water or dilute reagents. Many of the albuminoids, however, are insoluble. The proportion of soluble and insoluble albuminoids in alfalfa was determined by digesting samples with a dilute solution of pepsin and hydrochloric acid.

"In the whole plant the percentage of protein insoluble in pepsin decreases until budding time. It then remains constant for 4 weeks, or until the first week of full flower. It then falls again, but remains practically constant until the end of the experiment. . . . The reason the percentage of pepsin-insoluble protein in the whole plant decreases as the plant grows older is easily understood when we recall that the ratio between the leaves and stalks is not constant, but widens as growth goes on. When, therefore, the plant is young and the leaves are abundant, the percentage of pepsin-insoluble protein is high. As the plant grows older, and the stalks increase more rapidly than the leaves, the percentage of the pepsin-insoluble protein is smaller."

The nuclein was determined in the plant, leaves, and stalks of alfalfa and other hays cut in 1897, and in wheat, peas, and alfalfa seed. The results obtained were as follows:

Nuclein in alfalfa and other plants and seeds.

Substance.	Leaves.	Stalks.	Seeds.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Alfalfa second crop, young.....	6.78	2.93	
Alfalfa, first crop, old.....	6.8	2.32	
Clover slightly spoiled.....	9.62	2.71	
Timothy, slightly spoiled.....	3.15	1.10	
Wheat, very young.....	4.04	1.55	
Wheat, ripe.....	3.90		
Oats, very young.....	3.48	1.58	
Oats, ripe.....	3.46	1.29	
Wheat 3 years old.....			1.35
Wheat, 1 year old.....			1.28
Peas.....			1.62
Alfalfa.....			7.13

"The results, taken in connection with those previously given, furnish sufficient evidence that the percentages of nuclein in the leaves and the stalks of alfalfa are invariable; that they are not affected by the age of the plant, by the season, or by the place of cutting. They show further that the leaves and stalks of other plants do not contain the same percentages of nuclein as alfalfa, though the percentages they do contain are constant. The constancy does not seem to be confined to leaves and stalks alone, for 2 samples of wheat seed, grown in different years, contain the same percentage of nuclein. Only one sample of clover was obtained, and that in an imperfect condition; the analysis can not therefore be depended on to show the truth for a perfect sample.

"The wheat contains little more than one-half as much nuclein as alfalfa, the oats contain about half as much, and the timothy less than one-half. . . .

"With these results in our possession, and until later work shall modify them, it may be stated as a law that each organ of a plant contains a definite and invariable percentage of nuclein which is different from that of any other organ, and that similar organs of different plants do not necessarily contain the same percentages of nuclein."

The function of nuclein is discussed at some length. As the author points out, nonalbuminoids can not be used in the formation of muscular tissue and the nuclein is not digested. The sum of the nonalbuminoids and the nuclein subtracted from the total protein shows the amount of true flesh formers present.

"In the whole alfalfa plant the percentage of true flesh formers decreases as the plants grow older. During the periods of budding and flowering the percentage was almost constant. The total weight per acre increased to the period of budding and then remained constant to the period of full flower; after that time there was a decrease."

The protein in the different extracts was studied in considerable detail, and the general deduction was that "in the whole plant and its parts, the protein of alkali extract is the highest, followed by the protein of the acid, water, and alcohol extracts, the crude fiber and the ether extract."

The author discusses the proximate composition of alfalfa, and the portion determined by difference in ordinary analytical methods.

The advantage of frequent cuttings is pointed out. A comparison was made of the yield obtained in various cuttings, the first of them being made very early.

"Each successive cutting becomes smaller in the yield per acre, and also in the percentage composition of the most valuable ingredients. It is therefore important to secure as much as possible of the first, and best crop. When the fact that the hay cut at medium bloom has about the same food value as that cut a week earlier, the evidence that alfalfa should be cut after budding becomes still stronger."

Digestibility of alfalfa cut at different periods of growth (pp. 55-60).—Digestion experiments made by artificial methods indicated that the average coefficient of digestibility of the total protein of the alfalfa in the whole plant was for the first crop 71, and the albuminoids 61; for the second crop the coefficient of the whole protein is 67, and of the albuminoids 61; and for the third crop about 60 and 43, respectively.

Experiments on the digestibility of alfalfa of different crops and cuttings were made with steers. The usual methods were followed. The average results are shown in the following table:

Digestion of alfalfa hay by steers.

	Dry matter.	Protein.	Fat.	Nitrogen-free extract.	Fiber.	Ash.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
First crop: average of first, second, and third cuttings.....	58.78	65.07	35.00	72.41	40.15	41.62
Second crop: average of first, second, and third cuttings.....	60.32	70.48	42.25	71.74	44.36	46.16
Third crop.....	58.17	69.30	41.51	71.00	34.30	44.25
Average of all.....	59.64	67.99	39.04	72.36	41.12	43.94
Mixed alfalfa, 1896.....	60.16	70.30	50.57	71.80	45.67	40.85

The author's conclusion is that the digestibility of alfalfa remains practically constant from the time of cutting to the period of full bloom.

The time to cut alfalfa for hay (pp. 61-65).—The yield and composition of alfalfa of different crops and cuttings is discussed.

"From what has gone before we may at least draw two general conclusions; alfalfa in passing from the budding stage to the stage of first full flower decreases, pound for pound, in food value; and the acre crop, in passing through the same stages does not lose any of its beef producing power. We may hold this conclusion to be right; that to insure a large yield of dry matter and the largest amount of albuminoids, alfalfa should be cut not earlier than the period of medium bloom, and not much later than the period of first full flower. This in most cases will be 2 or 3 weeks after the flower buds begin to appear. It will be a more serious error to cut too early than to cut too late."

Appendix (pp. 67-90).—In the appendix are given in tabular form the results of the individual analyses discussed in the preceding pages.

Summary of digestion experiments with Kafir (*Oklahoma Sta. Bul. 35, pp. 4*).—A number of experiments on the digestibility of Kafir corn and Kafir corn products by steers are very briefly summarized. Two trials were made with Kafir corn, but in all other cases 4 trials were made. The coefficients of digestibility are shown in the following table:

Coefficients of digestibility of Kafir corn products by steers.

	Dry matter.	Protein.	Ether extract.	Nitrogen-free extract.	Fiber.	Ash.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Shredded Kafir stover	56.3	30.5	79.3	58.2	67.0	19.0
Kafir corn, fed dry.....	41.7	45.6	44.8	40.8	45.4	63.9
Kafir corn, soaked	38.0	40.2	38.8	38.0	35.2	65.7
Kafir heads	24.3	12.3	31.1	30.8	27.4	53.6
Coarse Kafir meal.....	64.2	53.3	46.1	75.9
Kafir fodder	60.6	38.1	61.0	66.4	60.4	7.8

"Kafir corn stover contained as much digestible matter as corn stover.

"Kafir corn fodder contained 10 per cent less of digestible matter than corn fodder.

"Kafir corn heads contained one-third as much digestible matter as corn-and-cob meal. Kafir corn fed in the heads was neither more nor less digestible than when fed after thrashing.

"Kafir corn fed after soaking in water for 12 hours was less digestible than when fed dry. Fed dry it contained 40 per cent less digestible matter than coarsely-ground Kafir corn meal.

"Kafir corn meal, coarsely ground, contained 20 per cent less digestible matter than corn meal. It paid to grind Kafir corn. One hundred pounds of Kafir corn meal contained as much digestible matter as 160 lbs. of Kafir corn.

"A gain of 13 per cent in the amount of digestible matter was secured when Kafir corn fodder was thrashed, the grain ground and fed to steers with the shredded stover from the fodder. A gain of less than 2 per cent in the amount of digestible matter was secured when Kafir corn fodder was thrashed and the grain fed to steers with the shredded stover from the fodder."

In addition to the above, brief notes are given on the steer-feeding experiments made in 1897 and 1898.

The steers fed Kafir corn heads made an average gain of 1.85 lbs. per day; those fed Kafir corn meal, 2.36 lbs. daily. Horses, cows, sheep, and pigs have kept in good health and made fair gains when the

only grain fed was Kafir corn, although in no case were as large gains made by pigs on Kafir corn as on corn meal.

"The loss from failure to digest all the food eaten is much less when hogs are fed unground Kafir corn than when cattle are so fed. In some cases hogs made less gain on soaked Kafir corn than when it was fed dry—probably because they ate the latter more slowly and masticated it more thoroughly.

"Running whole Kafir cornstalks through the thrashing machine puts the stover in excellent condition for feeding. Cracking some of the grains in the process of thrashing tends to increase percentage digested, if fed unground.

"This station has not succeeded in getting large gains with steers fed whole cotton seed as sole grain, but making cotton seed a part of the grain ration has given good results in a number of cases.

"From May 9 to September 1 of this year 9 yearling steers on pasture made an average gain of 160 lbs. each. During September, when fed reasonably near full feed of corn, still on pasture, they averaged a gain of 73 lbs. each. Taken from pasture and put on full feed of corn meal, with dry rough forage, they made little gain for first 3 weeks of October, probably partly because of carrying less weight in stomach. . . .

"Somewhat limited trials in feeding stock melons show them to be much liked, especially by hogs. Having a fair feeding value, being well suited to serve as a corrective of the bad effects of exclusive grain feeding to hogs, their large yield and the readiness with which they can be harvested, make it probable that they may wisely be substituted for root crops in Oklahoma, in part at least."

Feeding experiments at Mains of Laithers, 1897, A. P. AITKEN (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 10 (1898), pp. 259-280*).—Experiments on the comparative value of concentrated feeding stuffs, which are in continuation of work previously reported (*E. S. R., 9, p. 476*), were made with 5 lots of cattle. Each lot was made up of 8 Irish-bred and 2 home-bred animals. Lots 1 to 3 contained 6 heifers and 4 steers, and lots 4 and 5, 5 of each sex. The test began January 14, 1897, and covered 16 weeks. It was preceded by a preliminary period of 1 week under the same conditions as the experiment proper. All of the lots were given 80 lbs. per head daily of turnips and oat straw *ad libitum*. Sixty pounds of the turnips were fed sliced and 20 lbs. pulped. The straw was fed in 8-lb. bundles and the amounts eaten recorded. In order to compare the concentrated feeding stuffs on a financial basis the lots were fed an amount of the different materials which could be purchased for the same price as 5 lbs. of linseed meal. Lot 1 was given per head daily 6 $\frac{3}{4}$ lbs. of decorticated cotton-seed meal and dried brewers' grain 1 : 1; lot 2, 5 lbs. linseed meal; lot 3, 7 $\frac{1}{2}$ lbs. barley bran; lot 4, 6 lbs. barley; and lot 5, 6 $\frac{3}{4}$ lbs. maize. It became evident that too large an amount of barley was fed to lot 4 and the quantity was after a time reduced to 4 lbs. In every case account was taken of any uneaten residue of the ration. The feeding stuffs were all analyzed. The nutritive ratio of the rations fed the several lots was as follows: Lot 1, 1 : 5.5; lot 2, 1 : 6.3; lot 3, 1 : 8.7; lot 4, 1 : 10.8, and lot 5, 1 : 11.7. Each lot weighed about 9,800 lbs. The average daily gain per head for the different lots was as follows: Lot 1, 1.51 lbs.; lot 2, 1.47 lbs.; lot 3, 1.41 lbs.; lot 4, 1.28 lbs., and lot 5, 1.41 lbs. The experiment is reported and discussed in considerable detail.

“One of the objects of these experiments was to discover whether the feeding values of the by-fodders used were in harmony with their market prices. Last year it was found that they were pretty far out, and that linseed cake was on the whole the dearest. This year, when the amount of turnips fed was raised from 50 to 80 lbs. per head per day and the by-fodders reduced by one-fourth, the discrepancy between market price and feeding value is not so great, and linseed cake is no longer the dearest. The results of the experiment have been such as to enable us in their interpretation to take a wide range, and to afford information of a kind more valuable than can be obtained from a consideration of the mere question of price in relation to feeding value. Prices are constantly varying, and feeding value is seen to be a much more complex thing than would appear from the sole consideration of increase of live weight.

“The results of the 2 years' experiments have brought into prominence the supreme importance of the quality of the turnips grown upon the farm as a determinant of the feeding progress of the stock. The quantity eaten in 1897 was greater than in 1896, but on the other hand there was a considerable diminution in the quantity of by-fodders. On both occasions the quantity of by-fodders eaten was as much as the cattle could conveniently consume along with their turnip supply, but owing to the superior quality of the turnips the actual amount of true food derived from that source was practically doubled in the latter year, and it is to that circumstance that we must ascribe their greatly enhanced progress.”

Sheep feeding experiments at Ferney Castle and Whitelaw, 1897. A. P. AITKEN (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 10 (1898), pp. 281-292*).—In continuation of previous work (E. S. R., 9, p. 477) the author reports experiments with sheep made at Ferney Castle by A. S. Logan and at Whitelaw by A. G. Spence, to compare oil cake and grain when fed in addition to a full ration of turnips. In each case the tests were made with 4 lots of 20 grade sheep. The lots were carefully selected and were regarded as very nearly uniform. The experiment at Ferney Castle began February 3, 1897, and covered 86 days; that at Whitelaw began February 5 and covered 85 days. In both tests lot 1 was fed decorticated cotton-seed cake and dried brewers' grains 1:1, lot 2 linseed cake, lot 3 bruised oats and barley 1:1, and lot 4 bruised oats and maize 1:1. The concentrated foods were given at the rate of 1 lb. per head daily, each farm being supplied from the same source. The linseed cake fed to lot 2 was after a time reduced to $\frac{3}{4}$ lb., since the amount at first fed was evidently too large.

“At Ferney Castle the sheep were penned on turnip land, and were shifted about as the land grew foul, and during the last 3 weeks they were kept on lea. They were fed all the time on Swedish turnips. At Whitelaw the lots were penned on turnip land and fed on yellow turnips till the middle of March; thereafter they were shifted onto lea, and from March 25 till the close of the experiment they were fed on Swedish turnips.”

The composition of the foods is reported, as well as the amounts consumed and gains made by the different lots. At the close of the test the sheep were slaughtered and the weights of the carcasses, tallow, and wool are recorded. The average gains in weight per head for the different lots were as follows: At Ferney Castle, lot 1, 21.8 lbs.; lot 2, 21.6 lbs.; lot 3, 9.6 lbs.; and lot 4, 11.2 lbs. At Whitelaw, lot 1, 28 lbs.; lot 2, 29.1 lbs.; lot 3, 16.4 lbs., and lot 4, 14.3 lbs. The average dressed

weight for the 4 lots was as follows: At Ferney, lot 1, 69.2 lbs.; lot 2, 67.3 lbs.; lot 3, 59.6 lbs., and lot 4, 61.5 lbs. At Whitelaw, lot 1, 67.7 lbs.; lot 2, 67.4 lbs.; lot 3, 61.5 lbs., and lot 4, 61.8 lbs. The experiments are discussed in considerable detail.

"The results of the experiment are satisfactory, in that they show that there is very little difference in the feeding effect of linseed cake on the one hand and a mixture of cotton cake and dried grains on the other, when given to sheep in as great quantity as they can consume along with a full supply of turnips. As regards a mixture of oats and barley and a mixture of oats and maize, these also are fairly equal in feeding effect when given in equal quantities, although on the whole the advantage lies with the latter mixture. But oats, barley, and maize are evidently much inferior to the more concentrated by-fodders cotton cake and dried grains and linseed cake, and, as prices usually go, there is no economy whatever in feeding sheep with oats and barley. It would be better to sell these and buy concentrated fodder with the proceeds. The amounts of loose tallow and wool deserve notice. At both farms lots 1 and 2 produced the most wool, showing that the more highly nitrogenous dietary is favorable to wool production; and it is noteworthy that the oats-and-maize lot produced most tallow and least wool at both farms, not only on this occasion but also in the case of the former experiment."

The by-products of the dairy, F. B. LINFIELD (*Utah Sta. Bul. 57, pp. 197-219, figs. 9*).—In the author's opinion the usual methods of feeding pigs at creameries on milk or whey alone and finishing on grain for a short period is not satisfactory. Experiments were therefore undertaken to determine the value of skim milk and grain fed in various ways for pigs and calves.

Experiments in pig feeding (pp. 197-236).—Seven tests are reported extending over a number of years. The object was to compare the economy of feeding milk alone and in combination with grain as compared with grain alone. No comparison was attempted of the different grains fed. The composition of the foods used is reported, some of the analyses being made at the station. The first test which began June 27, 1894, covered 161 days, and was made with 2 lots of 4 and 1 lot of 2 pigs. Lot 1 was fed a ration of 1 lb. of grain to 4 of milk for the first 118 days and 1 lb. of grain to 2 lbs. of milk until the close of the test. Lot 2 was fed 1 lb. of grain to 2 lbs. of milk for 118 days and 1 lb. of grain to 1 lb. of milk for the remainder of the test. Lot 3 was fed grain mixed with water. For about three-fourths of the test the grain consisted of barley and bran 1:1; during the remainder, corn and wheat 1:1. The second test began January 5, 1895, and covered 135 days. It was made with 2 lots of 4 pigs each. Lot 1 was fed 4 lbs. of skim milk to 1 of grain until the pigs averaged 100 lbs. The proportion of skim milk was decreased as the pigs increased in weight until the pigs averaged 200 lbs., when they were fed skim milk and grain in equal amounts. Sufficient water was added to the grain to make up for the skim milk omitted. Lot 2 was fed grain mixed with water. The grain fed both lots consisted of wheat and bran 1:1. The third test, which began August 5, 1895, and covered 175 days, was made with 2 lots of 2 pigs each. Lot 1 was fed 6 lbs. of skim milk to 1 lb. of grain until the pigs

averaged 50 lbs. The proportion of skim milk was diminished, and from the time the pigs averaged 200 lbs. until the close of the test it was fed in the ratio of $\frac{1}{2}$ lb. to 1 lb. of grain. The skim milk and grain were fed in the form of a mash, the necessary amount of water being used as the skim milk was diminished. An attempt was made to feed lot 2 on skim milk alone, but the supply was not sufficient for the purpose, so some grain was necessary. The amount fed was 2 lbs. per day. The grain fed both lots consisted of wheat and bran 1:1. The fourth test was made with 3 lots of 2 Berkshire-grade pigs each. It began June 15, 1896, and covered 24 days. Lot 1 was fed 6 lbs. of skim milk to 1 lb. of grain until the pigs averaged 50 lbs. each. The amount of skim milk was diminished as the pigs increased in weight. From the time they averaged 100 lbs. in weight until the close of the test 2 lbs. of skim milk was fed to 1 lb. of grain. Lot 2 was fed skim milk alone, and lot 3 grain mixed with water. The fifth test, which was a continuation of the fourth, began January 14, 1897, and covered 102 days. It was made with 3 lots of 3 Berkshire or Berkshire-grade pigs each. Lot 1 was fed 5 lbs. of skim milk to 1 lb. of grain until the pigs averaged 75 lbs. in weight. The proportion of skim milk was then diminished, 3 lbs. to a pound of grain being fed. Lot 2 was fed skim milk alone *ad libitum*, and lot 3 grain mixed with water. Tests 6 and 7 began July 7, 1897, and were made with 3 lots of 3 Berkshire and Poland China-grade pigs. The results as tabulated cover 104 days. In each test lot 1 was fed skim milk or whey alone, lot 2 skim milk or whey and grain in the proportion of 5 lbs. of milk or whey to 1 of grain, until the pigs averaged 75 lbs. in weight. The proportion was then diminished to 3 lbs. of milk or whey to 1 lb. of grain as the pigs increased in weight; lot 3, grain alone mixed with water. In all the tests except No. 6, the pigs were fed in pens. In No. 6 they were pastured, the special object being to compare pasturage with feeding in pens with lots 6 and 7. The financial statement is based on grain at 75 cts. per pound, this being regarded by the author as a fair average for the 4 years covered by the investigation. The results of all experiments, which are given in detail, are summarized as follows:

Summary of tests of feeding skim milk to pigs.

Food.	No. of tests.	No. of hogs.	Time covered by tests.	Average weight at beginning.	Average gain.	Food eaten per pound of gain.		Dry matter eaten per pound of gain.	Gain per 100 lbs. milk eaten.
						Grain.	Milk.		
			Days.	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.
Milk and grain.....	8	27	133	40	169	2.92	7.68	3.34	23.2
Grain.....	5	15	121	63	110	4.70	4.21
Milk.....	4	11	108	39	74	33.12	2.98	14.2

The experiments are discussed at length and are summarized as follows:

"(1) Skim milk when fed in combination with grain makes a very valuable food for hogs at all periods of their growth, but particularly so during the earlier periods.

"(2) Skim milk and grain in combination make a much more economic ration for hogs than either milk alone or grain alone. The milk-and-grain-fed lots required 2.58 lbs. of digestible matter, the milk-fed lots 2.85 lbs., and the grain-fed lots 3.19 lbs. to make 1 lb. of gain in live weight.

"(3) When fed in combination with grain, skim milk has 63 per cent greater feeding value than it has when fed alone, 100 lbs. of skim milk taking the place of 23.2 lbs. of grain in the former case and 14.2 lbs. in the latter.

"(4) The hogs fed on the milk-and-grain ration made much more rapid gains than either those fed on milk alone or grain alone. The time required to make 100 lbs. of gain was 79 days for the hogs fed on milk and grain, 116 days for those fed on grain alone, and 117 days when the food was milk alone.

"(5) When the skim milk and grain were fed in the proportion of 3 lbs. or less of skim milk to 1 lb. of grain, the return for the skim milk was greater than when a larger proportion was fed. When fed in the proportion of 2 lbs. of skim milk to 1 lb. of grain, 100 lbs. of milk took the place of 31 lbs. of grain, but when fed in the proportion of 4 lbs. of skim milk to 1 lb. of grain, only 21 lbs. were displaced.

"(6) Hogs fed on milk alone gained very slowly and did not keep in good health; in some cases they were off their feed so frequently that a change of feed had to be made. The milk and grain fed hogs, however, without exception, kept in good health.

"(7) Young hogs fed on grain alone did not do well and appeared to make poor use of the food they ate. The hogs on this ration required 2.92 lbs. of digestible matter to make 1 lb. of gain at an average weight of 73 lbs., and only 2.83 lbs. when they weighed 127 lbs. When the food was changed to milk and grain a marked improvement was effected in their growth and thriftiness.

"(8) Those hogs fed on milk alone or grain alone when on pasture, did much better than hogs similarly fed in small pens. The milk-fed lot, on pasture, gained 0.05 lb. more per day and required 0.54 lb. less dry matter to 1 lb. of gain than did the lot fed in pens, and the grain-fed lot, on pasture, gained 0.3 lb. more per day and required 0.88 lb. less of dry matter to each pound of gain. On the other hand, however, the hogs fed milk and grain in combination did better in the pens, gaining 0.05 lb. more per day than did those on pasture and required practically the same amount of food to make a pound of gain.

"(9) The appetite of the hogs and the palatability of the food seemed to have a very beneficial effect upon the rapidity and economy of the gain. The milk-and-grain-fed hogs ate 0.37 lb. more digestible matter per day than those fed on grain alone, and 1.46 lbs. more than those fed on milk alone. They gained 0.41 lb. per day more than the hogs fed grain alone and 0.59 lb. more than those fed milk alone. They also required 0.51 lb. less digestible matter for each pound of gain than did the hogs fed grain alone and 0.27 lb. less than the hogs fed milk alone.

"(10) Young hogs are in every way the more economic producers of pork. The hogs fed milk and grain required 62 per cent more to grow a pound of live weight when they weighed from 200 to 255 lbs. than they did when they weighed from 38 to 100 lbs. and for those hogs fed on grain alone the difference in favor of the smaller weight was 56 per cent."

Experiments in calf feeding (pp. 237-246).—Tests extending over 4 years were made with 16 calves to learn the relative value of skim milk and whole milk. In all the tests the calves were fed separately in stalls. In every case they were separated from the cow when 12 hours

old. For from 7 to 10 days all the calves were fed 16 to 18 lbs. of whole milk daily. As the calves grew older the amount given those which were to be kept on whole milk was increased to 20 to 22 lbs. per day. They were disposed of when 1 month old. Skim milk was substituted for whole milk in the ration of the skim-milk calves when they were from 7 to 10 days old, the amount fed being gradually increased. When 4 or 5½ weeks old, skim milk only was fed, the maximum amount being 25 to 27 lbs. daily. They were given water in addition to the milk. The skim-milk ration was continued until the calves were 5 or 6 months old. In every case fresh separator skim milk was used. It was kept from souring by heating, and was fed at 80 to 100° F. As soon as the calves would eat it, they were given a little dry chopped grain. The grains used were wheat and bran, barley and bran, barley, peas and bran, corn and bran, and corn. No comparison of the grains was made, but it is stated that one did not prove to be more satisfactory than another. After the calves were 2 or 3 weeks old they were given a little hay, usually alfalfa. The average results of all the tests are shown in the following table:

Summary of tests of feeding skim milk to calves.

	Food eaten (average).				Average weight at beginning.	Average gain per day.	Food consumed per pound of gain.				Ratio of dressed weight to live weight.
	Milk.		Skim milk.	Grain and hay.			Whole milk.		Skim milk.	Grain and hay.	
	Lbs.	Fat.					Milk.	Fat.			
Two calves fed whole milk	Lbs. 671	Lbs. 26.30	Lbs.	Lbs.	Lbs. 70	Lbs. 2.10	Lbs. 9.50	Lb. 0.37	Lbs.	Lb.	Per ct. 65.0
Seven calves fed whole milk and skim milk	232	9.06	536	76	1.77	3.60	.14	8.3	58.3
Seven heifer calves fed whole milk and skim milk	181	7.60	453	5.7	71	1.44	3.46	.14	8.6	9.11

Eight of the calves were sold for veal and the percentage of live weight to dressed weight recorded. The feeding of the heifer calves was continued. They were fed about 20 lbs. of skim milk daily with hay and grain. The food eaten and the gains made are recorded as well as the food consumed per pound of gain.

The labor cost of feeding calves and hogs (pp. 247-249).—The author discusses the cost of the labor of feeding pigs and calves.

"We find that it costs 5 hours of labor, or 50 cts., to look after 500 hogs for 1 day, or \$50 to look after 500 hogs for 100 days. This is 10 cts. for 1 hog for 100 days, or for 100 lbs. gain, which gives 0.1 ct. as the labor cost of producing 1 lb. of live weight of hog. It is thus evident that when handled in large numbers, as hogs may be at a creamery, the labor is a very small item in growing the hogs. If the value of the gain was reckoned at 4 cts. per pound, the labor cost of producing the pork was but 2½ per cent of its selling price.

"The above, of course, represents almost ideal conditions, yet it is what any factory operator could do with very little outlay.

"The remarks are equally applicable to calf feeding as to hog feeding. Though perhaps it would be more difficult to feed a large number of calves than a large number of hogs. One of the best devices noticed for handling a large number of calves was a row of stanchions along one side of a pasture with a trough on the outside divided into boxes, one for each calf. At feeding times each calf was fastened in a stanchion, given his share of milk, and left there till he had gotten over his tendency to suck any of his mates. If the calves were divided into lots according to age and the lots fed separately, it would probably simplify matters."

Experiments with geese, C. O. FLAGG (*Rhode Island Sta. Rpt. 1897, pp. 181-617, figs. 25*).—The earlier work of the station with geese is cited, and experiments made in 1896 are reported in much greater detail than in the preceding Annual Report of the station (E. S. R., 10, p. 979). In the experiments with geese the eggs of different breeds and crosses were marked and the goslings when hatched were permanently marked by punching one or more small holes through the membrane of the foot. The majority of the experiments in 1897 were made with the same breeding stock as in the previous year with the addition of some African and Embden stock. A new mating was made to secure pure Toulouse goslings, and 2 crossings of White and Brown Chinas were made. The weights of the eggs at the beginning of the experimental period in January were recorded as well as the eggs laid by the different breeds and crosses. A table is given summarizing the weights of eggs laid by the different breeds in 1896 and 1897.

"Africans laid the largest eggs, averaging practically 6.7 oz. each. Embdens rank next in order, averaging 6.567 oz. each. The eggs of Toulouse geese averaged 6.3 oz. each; those from White Chinas 5.522 oz. each, and those from Brown Chinas were smallest in size, averaging but 5.415 oz. each. These averages are the result of weighing from 155 to 250 eggs in each instance, and fairly represent the difference in size in the eggs from the different breeds. Eggs from African geese would average to weigh 5.025 lbs. per dozen, which is 3.1 times the average weight of Rhode Island Red and Plymouth Rock hens' eggs as determined by weighing 10 doz. selected for hatching." (Average weight 1.62 lbs.)

The loss of weight of eggs during incubation was tested. The eggs were weighed and placed in incubators. After 7 days they were weighed and tested; those which were found to be infertile were removed. On the 22d day of the incubation period the eggs were again weighed, removed from the incubator, and placed under hens. The goslings were weighed as soon as hatched.

"The average weight of the 3 eggs from which goslings were hatched was 6.0053 oz. at the beginning of incubation, and the average weight of the goslings when hatched was 3.8913 oz., showing an average loss of 2.114 oz. during incubation. The individual losses were as follows: Egg No. 4 lost in hatching, 1.9827 oz., egg No. 6, 2.1719 oz., and egg No. 7, 2.1875 oz. The gosling from egg No. 4 was the only vigorous one, but whether the smaller amount of evaporation from that egg had any relation to the vigor of the gosling we can not say."

The average loss in weight of 12 fertile eggs was 0.3369 oz., of 9 infertile eggs 0.3437 oz., of 3 fertile eggs which hatched out goslings 0.3204 oz., and of 9 fertile eggs which did not hatch 0.3425 oz.

The percentage of goslings hatched in 1897 was in all cases low; in the author's opinion much lower than is usually secured by practical goose breeders where the breeding stock is not confined and the eggs are set very soon after laying.

"In these experiments the percentages are considerably reduced by the poor success of the White China matings, which the practical breeder should avoid. [The percentages for the year shows] that the Africans, as a breed, both males and females, have given the highest percentage of goslings from eggs set, the average for the breed being 38.09 per cent. This breed also shows the lowest percentage of infertile eggs—32.18 per cent., Toulouse rank second, Embdens third, Brown China fourth with a per cent of 28.57, and White China last with a hatch of 10.8 per cent of the eggs set."

The goslings were fed and cared for in practically the same way as in the previous year, the green feed being probably less abundant. They were weighed when about 5, 8, and 10 weeks old and the weights recorded for comparison. The weights of the different goslings are recorded in full in tabular form, and the growth of the different breeds in the different periods is discussed in detail.

"In 1897 pure Toulouse ranked first in average weight at about 5 weeks old, and crossbreds held the next three or more places. At 8 weeks old pure-bred Africans held the third place, and crossbreds held the other three of the four greatest average weights. At about 10 weeks old Africans held the first place, having the highest average weight, the daily growth being equal to 2.28 oz., as against 2.24 oz. per day for the Embden-African cross, which held first place at the same age in 1896. Crossbreds held the next three or more places at 10 weeks old. No pure White China or Brown China matings were made in 1897 and the lowest average weight recorded at each of the 3 weighings was for the White China-Brown China cross."

The loss of weight in dressing and drawing was determined with a number of geese. The figures indicate that—

"There is less than 5 per cent loss in live weight in the process of dressing for market in the case of geese, and over 13 per cent in the case of hens. . . . The greatest shrinkage between live and drawn weight is found in the case of an Embden-Toulouse cross, where the drawn weight was only 63.94 per cent of the live weight. The least shrinkage is . . . recorded in the case of the White China-Brown China cross, where the drawn weight was 76.05 per cent of the live weight. The average percentage for 19 geese from 9 different matings was 68.11, showing a shrinkage from live to drawn weight of 31.89 per cent. The average shrinkage between live and dressed weight was 4.88 per cent."

Thirteen goslings were exhibited at the Rhode Island Poultry Association Show and the percentage of skin and skin fat, flesh, bones, and offal in each was determined by Prof. Bumpus, of Brown University. The results are given in full in tabular form. The percentage of lean meat varied from 32.4 in the case of the Embden-Toulouse to 38.2 for the White China-Embden. The percentage of skin and skin fat was largest in the case of the Embden-Toulouse (21.6 per cent), and smallest in that of the White China-Embden (9.1 per cent), showing the former to have been very well fattened while the latter was the poorest among the number. The percentage of bone was smallest in the case of the

Embden-Toulouse and next lowest in the case of the Toulouse-African. The bones varied in weight from 9 oz. in the case of the Embden-Brown China cross, to 19 oz. in the Embden-African cross. "In the latter case the bones represented 7.2 per cent of the live weight. The head, feet, wings, and intestines, with the contents of the gizzard, representing the shrinkage in drawing, varied from 20.5 per cent of the live weight, in the case of a Brown China-Embden cross, to 23.9 per cent in the Embden-African cross. The percentage of offal was remarkably uniform, there being a variation of only 3.4 per cent."

The influence of one white parent in cross breeding geese is discussed at considerable length, as well as the influence of Toulouse blood in the production of goslings with yellow bills. The market quotations of geese in 1897 are summarized.

The food of man at the present time and in the future, E. BEKETOW (*Pitanie cheloryeka v ego nastoyashchen i budushchem. Moscow, 1896, ed. 2., pp. 48*).

Digestive ferments, with especial reference to the effects of food preservatives, H. LEFFMANN (*Jour. Franklin Inst., 147 (1899), No. 2, pp. 97-108*).—The experiments reported have been noted from another publication (E. S. R., 10, p. 170).

Tables for computing rations for farm animals, J. L. STONE (*New York Cornell Sta. Bul. 154, pp. 135-154*).—The terms used in discussing the composition of feeding stuffs and mixing of rations are defined. Feeding standards are quoted, and a table is given showing the amount of digestible dry matter and digestible nutrients in a number of common feeding stuffs, in quantities ranging from one pound to a number of pounds. The quantities selected are such as would prove useful in compounding rations.

The differentiating characteristics of the products of pepsin and pancreatic digestion of fibrin, V. HARLAY (*Jour. Pharm. et Chim., 6. ser., 9 (1898), No. 5 pp. 225-232*).

The curing of bacon (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1897, pp. 87-97, dgm. 1*).—The method of curing bacon in England is described in considerable detail, an article by L. M. Douglas in the Journal of the Royal Agricultural Society of England being quoted.

Bacon curing from the English point of view, L. M. DOUGLAS (*Agr. Gaz. New South Wales, 10 (1898), No. 12, pp. 1408-1420, figs. 2, pls. 3*).—This article, reprinted from the Journal of the Royal Agricultural Society of England, is noted above from another source.

Goose breeding, C. O. FLAGG (*Rhode Island Sta. Rpt. 1897, pp. 409-480, figs. 10*).—This is a general discussion of the subject with many references to the literature. The principal topics treated are peculiarities of geese, varieties, improvement of breeds, marking, cross breeding, the goose industry in Rhode Island, marking geese, location for breeding, mating, care of geese, feeding and management, rearing of goslings, fattening, killing, and picking, the production of mongrels, and goose raising in Sweden.

DAIRY FARMING—DAIRYING.

A feeding experiment with rations consisting of forage only and of forage and feed, E. B. VOORHEES and C. B. LANE (*New Jersey Stas. Bul. 130, pp. 16-22*).—In this experiment oats and peas fed alone were compared with the same fed with 5 lbs. of wheat bran and 3 lbs. of dried brewers' grains. One hundred pounds of the forage was used

when fed alone and 60 lbs. when fed with the grain, giving rations practically identical in the amount and proportion of nutrients. Two lots of 2 cows each were used and the feeding covered 2 ten-day periods, the lots being reversed in the second period. The 2 lots produced on the forage ration 1,021.9 lbs. of milk and 38.2 lbs. of butter fat, and on the forage-and-grain ration 1,091.4 lbs. of milk and 42.9 lbs. of butter fat, a gain on the forage-and-grain ration of 6.8 per cent of milk and 12.3 per cent of fat.

With oats and peas at \$2 per ton, wheat bran at \$16.50, and dried brewers' grains at \$17, the milk was produced at 39 cts. per hundred on forage alone and at 46 cts. per hundred on forage and grain, or an increase of 18.7 per cent in the cost of milk production on the latter ration.

"The results of this experiment indicate that green forage of the same general composition as oats and peas may serve as an entire ration for dairy cows without injury to the animals and at a considerable saving in the cost of milk, though the yields may be slightly reduced."

Experiments with milch cows on the effect of work on the yield and composition of the milk, A. MORGEN ET AL (*Landw. Vers. Stat.*, 51 (1898), No. 2-3, pp. 117-151).—The experiments included 2 young cows and covered 11 periods of 14 days each. In alternate periods the cows were worked in a power machine, not exceeding 1 to 2 hours daily. It was found that as a result of moderate work the yield of milk decreased (on an average 0.7 kg. per day), this decrease being due to a diminution in the water, since the milk was more concentrated when the cows were worked. The principal effect was noticed on the percentage and total amount of fat, both of which increased, the percentage increase in the fat content being 10.7 per cent. The percentage of total solids increased, but not in proportion to the fat content, as the solids-not-fat decreased somewhat. The absolute amount of total solids decreased. There was also a decrease in all of the constituents of the solids except the fat, and especially in the case of milk sugar. Within the limits of the experiment, the larger amount of work (2 hours) did not affect the milk more than the smaller amount. There was only a slight effect noticeable on the live weight.

Composition and nutritive value of different kinds of cheese, BALLAND (*Compt. Rend. Acad. Sci. Paris*, 127 (1898), No. 22, pp. 879-881).—Ordinary cheese is said to contain 80 per cent of water and a larger amount of proteids than of fat. The so-called "cream" cheeses (as Neufchatel) contain from 50 to 60 per cent of water, more fat than proteids, and very little ash. "Half salted" cheeses are more solid, contain less fat and more ash (1 to 2 per cent). Salted soft cheese contains from 4 to 5 per cent of ash, 30 to 50 per cent of water, and varying percentages of fat and proteids, according to the variety. Hard

cheeses (Chester, Swiss, Holland, Roquefort, etc.) have a more uniform composition. The water content does not exceed 30 per cent, the salt content 4 to 5 per cent, and the fat and proteids are often equal. The nutritive value of such cheese is very great, 100 gm. of Swiss cheese containing as much fat and proteids as 1 liter of milk and more than 250 gm. of meat, with 75 per cent of water. It is suggested that cheese with bread would make a good food for army uses.

Trial of milking machines, J. DRYSDALE (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 10 (1898), pp. 166-181, figs. 5*).—A report of a committee of the Highland and Agricultural Society appointed to conduct a trial of milking machines for a premium of £50. The manufacturers of the Murchland and Thistle machines entered the competition. The committee selected 7 farms on which these machines were in daily operation, 3 using the Murchland and 4 the Thistle. These farms were visited, the operation of the machines observed, and samples of the milk taken for testing their keeping qualities in comparison with hand-drawn milk.

The committee awarded the premium to the Murchland machine. "it having in every respect the most effectually fulfilled the conditions which they originally agreed should guide them in making their awards."

"In every instance the samples of milk drawn by this machine were found to keep satisfactorily. After a lapse of 48 hours they were found in no respect inferior to the samples of milk drawn by hand; in fact, if anything, rather superior in point of flavor. The committee regard the Murchland machine as a practical success, and are of opinion that in large dairies where there may be difficulty in obtaining milkers it may be introduced with advantage. . . . The chief defect in [the Thistle] machine is the effect it has on the keeping qualities of the milk. The committee found that in every case the milk drawn by it kept unsatisfactorily, most of the samples developing sourness and bad flavor in from 12 to 14 hours and marked or great acidity in 24 hours, while samples drawn by hand from the same cows at the same time, and kept under precisely the same conditions, remained perfectly sweet for from 36 to 50 hours."

In conclusion an illustrated description is given of the Murchland machine and its mode of working.

The persistence of bacteria in the milk ducts of the cow's udder, A. R. WARD (*Jour. Appl. Micros., 1 (1898), No. 12, pp. 205-209, fig. 1*).—In studies of the foremilk of a cow 4 or 5 species of bacteria were found, only one of which was common to the 4 teats, but "the same species were found to persist in the same teat from day to day." The milk of another cow examined on 5 occasions covering a period of 8 months showed 3 species, streptococcus predominating in all of the teats at first, and persisting throughout the trial, although it diminished in proportion. No streptococci were found in the milk of 8 other cows in the same stable.

An experiment was made in colonizing the milk cistern of a cow with *Bacillus prodigiosus*, introduced with a hypodermic syringe lengthened with a milking tube. The bacillus was found in the milk for 5 days after its introduction, although the number of colonies decreased from day to day, and the bacillus disappeared on the sixth day.

Bacteriological examinations were made of the glandular tissue of the apparently healthy udders of 6 cows, together with the foremilk of these cows just before they were slaughtered. The udders were divided arbitrarily into three parts, the teat and cistern, the middle part above the cistern, and the part above the middle. It was found by cultures that—

“The same organism frequently occurred in the foremilk and in each of the three parts of the udder. Most of the bacteria obtained in pure cultures were found to belong to one of three micrococci. . . . The evidence at hand indicates that the teats and the greater portion of the udder may normally contain bacteria. It also seems highly probable that a few at least of the organisms found in the udder remain there after each milking, becoming the progenitors of the organisms found to be present in the milk when drawn.”

Bacillus typhi abdominalis in milk and butter, H. L. BOLLEY and M. FIELD (*Centbl. Bakt. u. Par., 2. Abt., 4 (1898), No. 24, pp. 881-887*).—After a review of the literature of the subject the authors report the results of a large number of experiments in which sweet milk, sour milk, buttermilk, and butter were inoculated with typhoid cultures from different sources. These samples were examined for bacilli at different dates after the inoculation. From the results the authors conclude that typhoid bacilli may remain in butter in an active virulent condition for at least 10 days, and under many conditions probably for a much longer period, as, for example, butter containing a large percentage of buttermilk, which the experiments showed to be a good culture medium.

The presence of bacteria in butter, HORMANN and MORGENROTH (*Hyg. Rundschau, 8 (1898), No. 5, pp. 217-230*).—The authors' conclusions are as follows:

(1) The best method for detecting tubercle bacilli in butter is to inject 4 to 5 cc. of the butter melted at 37° C. into the peritoneal cavity of 3 guinea pigs. Cultures (at least 8 or 10) are made from the affected organs of the dead animals or those killed after 4 to 6 weeks, and parts of these organs are also introduced into the peritoneal cavity of 2 other guinea pigs and a rabbit. These latter animals are killed after 4 weeks, and blood serum cultures made.

(2) True tubercle bacilli not infrequently occur in butter.

(3) An acid-resistant bacteria is found in butter, which produces sickness in guinea pigs. This, however, is not likely to be mistaken for tubercle bacilli.

(4) From a hygienic standpoint the use of ordinarily prepared butter is open to question, and pasteurizing the milk or cream used for butter making is desirable.

Further contributions on the presence of tubercle bacilli in butter and cheese, HORMANN and MORGENROTH (*Hyg. Rundschau, 8 (1898), No. 22, pp. 1081-1084*).—Three additional samples of butter from different sources were tested, and one found to be infected with tubercle bacilli.

A sample of German Camembert cheese was mixed with water and injected into a guinea pig. The pig died within 24 hours of peritonitis. Fifteen samples of cottage cheese were tested, with the result that many of the animals died of peritonitis in 1 or 2 days; and 3 samples were found to be infected with true tubercle bacilli.

The rancidity of butter and the effect of pasteurizing cream on the keeping quality of butter, H. SCHMIDT (*Ztschr. Hyg. u. Infectiouskrank.*, 28 (1898), No. 2, pp. 163-188).—Different lots of butter from the same source were kept under a variety of conditions in light and darkness, and observations made on the germ content, the production of acid, the rancidity, taste, odor, etc. Salted and unsalted butter from unpasteurized cream and from cream pasteurized at 70 to 75° and 90 to 95° C. was used. It was found that the acidity and the germ content were appreciably lower in the salted and the pasteurized butter in proportion to the height of temperature employed in pasteurizing. Both the acidity and germ content were greater in butter kept in the dark than in the light at similar temperatures; but both were reduced by keeping in a refrigerator and increased by keeping in a breeding oven at 23° C. In sunlight with free access of air there was no increase in germ content and the germs were gradually destroyed. There was a slight increase in acidity, which is believed to be due to chemical action.

Under exclusion of air, both in darkness and diffused light, the acidity of butter from cream pasteurized at 90 to 95° exceeded that of butter from cream pasteurized at 70 to 75°. This was true of both salted and unsalted samples. The cause of this is not explained.

In general, butter with a high acidity was more or less rancid in taste and odor, but there were some exceptions to this rule, notably in butter kept in sunlight with free access of air. Such butter soon became rancid and greasy, lost its color, and was wholly inedible, although the acidity did not indicate it to be rancid, or only slightly so. Butter became rancid most rapidly in sunlight and next to that in the breeding oven (in darkness). Keeping in a refrigerator was the best protection against rancidity. Butter from ordinary cream became rancid more rapidly and to a greater degree than that from pasteurized cream, and the keeping quality of butter was increased by pasteurizing the cream at the higher temperature. Salted butter did not become rancid as soon or to so great a degree as unsalted.

The best conditions for keeping obtained in salted butter from pasteurized cream kept in a refrigerator. Such butter was normal after 15 days, only slightly rancid after 30 days, and was still edible when 70 days old.

Pure cultures for Cheddar cheese making, J. R. CAMPBELL (*Trans. Highland and Agr. Soc. Scotland*, 5. ser., 10 (1898), pp. 181-224).—A preliminary experiment in the use of a pure culture of lactic-acid bacteria proving satisfactory, experiments were made on a practical scale at Craigley during June, July, and August, the results of which

are reported in detail. In addition to the work at Craigley one or more cultures were sent to 32 cheese makers for trial. The more than 100 tons of cheese made with the pure culture was for the most part sold at satisfactory prices, indicating "that the bacterium selected has proved suitable for cheese making, though it does not mean that this particular bacterium is absolutely the best." When the culture was used in too large quantities it had a decided tendency to quick ripening. The ripened cheese made at Craigley was good, the quality not having been injured by the culture. The flavor was good and there was an absence of "the undesirable fodder taste common to spring cheese." The cheese makers to whom cultures were sent for trial were in the main satisfied, several of them using the cultures all summer and requesting that they be supplied with the same bacterium the following season. In several cases cheese made with the pure cultures was given prizes at exhibitions.

The author discusses the cause of ripening, stating that while his investigation "does not absolutely prove that the bacterium used in the pure culture is the sole cause of ripening," some special experiments with milk cooled to 61-65° F. go "far to show that ripening is caused by the bacterium in the starter."

Trials of the pure cultures in 2 dairies for the purpose of preventing discoloration of the cheese resulted favorably "and in a third dairy discoloration ceased as soon as the culture was used."

The bacterium used in the culture "agrees in all respects with Leichmann's bacillus, but differs essentially from the *Bacillus acidi lactici* (Hueppe)." It produced no gas when cultivated in sealed bottles of milk or in deep tubes of gelatin or agar. In sterilized milk it produced "a clean sharp acid such as cheese makers desire." When grown in milk with other bacteria "it invariably grew so rapidly that the products of the others were completely masked, or else the acid which it developed destroyed or checked the growth of these undesirable forms of ferments." The bacterium was compared with those found in sour milk, whey, cheese, and pure culture for ripening cream. The form was found to be very prevalent in sour milk, whey, and cheese of fine quality, and in all of the pure cultures for butter making which were examined a lactic-acid bacterium resembling the one used by the author was found. The author gives instructions for using the culture, preparing starter, etc.:

"The main result of this investigation, so far as it has extended, may be summed up in one sentence, namely, the use of a pure bacterial culture in cheese making has been proved both successful and practicable. There is every probability that the system may with great advantage be applied—

- "(1) Where there is danger of discoloration.
- "(2) Where there is difficulty in getting a firm dry curd.
- "(3) Where a starter of some kind is necessary, the conditions for keeping milk being at the same time imperfect.
- "(4) Where there is trouble from tainted milk or tainted curd.
- "(5) For the production of cheese in spring and autumn.
- "(6) For securing greater uniformity in quality.

"The system is not to be recommended for dairies described as 'quick,' unless efficient means for cooling the evening's milk exist. . . .

"Though there are a number of different bacteria which produce lactic acid when grown in milk, one form may always be found predominating in ripe milk, sour whey, and good cheese.

"For the manufacture of Cheddar cheese this bacterium, and this one only, is required for the fermentation both of milk and curd, and also for the ripening process."

The author promises further investigation on the subject.

VETERINARY SCIENCE AND PRACTICE.

Anthrax in the lower Mississippi Valley (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1897, pp. 166-178*).—In the spring and summer of 1896 there was an exceptionally widespread epidemic of anthrax in the northern part of Louisiana and adjacent regions. Statistics of the extent of the epidemic are quoted. The epidemic is discussed, and preventive and curative remedies employed and other matters concerning the epidemic are discussed. Preventive measures are regarded as more satisfactory than curative.

"The preventive measures recommended were on two lines:

"(1) The treatment of healthy living animals by a process of vaccination which, it was claimed, would render them immune to the disease, and the application to their bodies of a preparation to protect them from flies.

"(2) The application of such sanitary measures throughout the infected districts as would tend to destroy or neutralize, so far as possible, every condition favorable to the further increase and wider distribution of the microscopical plant life which is known to be the cause of this disease."

Enzootic cerebro-spinal meningitis in horses, and hog cholera in Idaho, W. L. WILLIAMS (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1897, pp. 179-187*).—In 1896 many horses and pigs in Idaho were affected with diseases which were in that region believed to be due to a common cause. The author reports a number of cases studied by him. The horses were affected with cerebro-spinal meningitis and the hogs with hog cholera.

"The common supposition that the two affections—of horses and hogs—are identical and due to a common cause, is sufficiently refuted by the *ante-mortem* and *post-mortem* examinations recorded herewith. It may be added, moreover, that no clinical or historical evidence of identity could be established through other obtainable facts."

Contagious diseases in European countries (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1897, pp. 69-86*).—Statistics are given of the contagious diseases of animals in Great Britain, France, Norway, Belgium, Hungary, Denmark, and Switzerland.

Cattle tuberculosis, T. M. LEGGE and H. SESSIONS (*London: 1898, pp. 78*).

Investigations relative to sheep scab (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1897, pp. 155-165*).—The article contains the reports of four inspectors who visited a number of sheep-feeding stations to find out the number of sheep fed, the conditions of the feeding stations, water, dipping vats, and the sanitary conditions of the sheds, with a view to determine whether the regulations relative to the transportation of sheep affected with scab were enforced.

Sheep scab: Its nature and treatment, D. E. SALMON and C. W. STILES (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1897*, pp. 98-149, pls. 6, figs. 36).—This is a reprint from Bulletin 21 of this Bureau (E. S. R., 10, p. 793).

A pneumo-enteric infectious disease of pigs in Portugal, A. R. MARTINS (*Arch. Med.*, 1 (1898), No. 3; *abs. in Centbl. Bakt. u. Par., 1. Abt.*, 25 (1899), No. 2-3, p. 89).—A study of epidemic diseases observed in swine in Portugal showed the presence of the swine plague.

Investigation of alleged rabies in Nebraska, W. H. GIBBS (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1897*, pp. 188, 189).—The report of a number of cases believed to be rabies, causing the loss of 14 hogs, 2 cows, 1 mule, and 1 horse, from what, in the author's opinion, was rabies communicated to them by dogs.

The identification of trichina, A. JOHNE (*Der Trichinenschauer. Berlin: Paul Parey, 1898*, 6. ed., pp. XIV+170, figs. 125).—This is described as a compendium for inspectors, meat-control officers, and veterinarians.

STATISTICS—MISCELLANEOUS.

Report of Florida Station for 1898 (*Florida Sta. Rpt. 1898*, pp. 72).—This contains reports of the director, agriculturist, chemist, biologist, horticulturist, and entomologist, parts of which are noted elsewhere, and a financial statement for the fiscal year ending June 30, 1898.

Tenth Annual Report of Rhode Island Station, 1897 (*Rhode Island Sta. Rpt. 1897*, pt. I, pp. 90-93; pt. II, pp. 111-644, I-XVII).—This includes the financial report for the fiscal year ending June 30, 1897; a brief report by the director; various articles noted elsewhere; lists of donations and exchanges for 1897 and station publications from date of organization; and an index of the bulletins and Annual Report for 1897.

Eighth Annual Report of Wyoming Station, 1898 (*Wyoming Sta. Rpt. 1898*, pp. 43-63, 85-342).—This contains reports of the director and heads of departments; the treasurer's report for the fiscal year ending June 30, 1898; and an appendix containing reprints of Bulletins 34-37 of the station on the following subjects: Fruit growing in Wyoming (E. S. R., 10, p. 44), Mechanical analysis and water content of Wyoming soils (E. S. R., 10, p. 29), Wyoming sugar beets (E. S. R., 10, p. 346), and The stooling of grains (E. S. R., 10, p. 947).

Experiment Station Work—VIII (*U. S. Dept. Agr., Farmers' Bul. 87*, pp. 32, figs. 6).—This number contains articles on the following subjects: Soil moisture, fertility of soils, cover crops for orchards, cultivating *vs.* cropping orchards, transplanting trees, fecundity of swine, food value of eggs, starch from sweet potatoes, and the toad as a friend of the farmer.

Fourteenth Annual Report of the Bureau of Animal Industry, D. E. SALMON, (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1897*, pp. 727).—This contains the report of the chief of the Bureau and a number of special articles on a variety of topics, some of them reprinted from other publications. A number of these articles are referred to in another place (pp. 992, 998). The report also contains statistics of the movement of farm animals, the range of prices in Chicago from 1891 to 1896, inspection and movement of sheep, animals imported for breeding purposes, imports of animals at quarantine stations, number and value of farm animals, and imports and exports of animals and animal products. Rules and regulations of the Bureau of Animal Industry, laws of States and Territories for the control of contagious animal diseases, and laws of States and Territories relative to dairy products, are also quoted. A list of the publications of the Bureau for the fiscal year 1897 is given.

Statistics of Ontario (*Ontario Bureau of Ind. Bul. 67*, pp. 24).—This contains meteorological observations and statistical tables on farm lands, field crops, live stock, population, etc., of Ontario compiled from the annual reports of the Ontario Bureau of Industries.

NOTES.

IOWA COLLEGE AND STATION.—P. T. Barnes, late of the New York State Station, has been placed in charge of the greenhouses. His time is divided between instruction and experimental work. The unusual cold of last winter, coupled with the light snowfall in central and southern Iowa, has caused great damage to nursery stock. This injury has come in the form of what is known to nurserymen as "root killing." In the college nurseries as well as in private nurseries thousands of trees have been killed and thousands badly injured. In the case of piece-root apple grafts the injury is confined mainly to that part of the root below the union of the scion and stock. Where roots have developed from the scion they are usually in good condition.

TEXAS COLLEGE.—Fred W. Mally, M. Sc., of Hulen, Tex., has been elected professor of entomology in the college. He will make the boll weevil the primary subject of investigation.

WASHINGTON COLLEGE AND STATION.—Plans and specifications have been adopted for the construction and equipment of Science Hall, to cost \$60,000. This building will provide quarters for the departments of botany, zoology, bacteriology, agriculture, horticulture, veterinary science, and geology, and the third story will be devoted to museums. Each department will have a professor's office, a lecture room, and from one to three laboratories. The building will be of pressed brick with stone trimmings, 170 feet long by 80 feet deep, and three stories high. Ferry Hall, the boys' dormitory, will also be built, at a cost of \$40,000. It will provide for from 175 to 200 students. David A. Brodie, a graduate of the college, has been chosen superintendent of the substation at Puyallup, which has been opened at State expense.

AGRICULTURAL COLLEGE AND EXPERIMENTAL FARM FOR NOVA SCOTIA.—An act passed at the last session of the provincial legislature authorizes the purchase of land for an agricultural college and experimental farm and the erection of suitable buildings, appropriating \$20,000 for the purpose. The college will take the place of the provincial agricultural school at Truro and the horticultural school at Wolfville. The grant for the maintenance of the horticultural school is to be discontinued with the establishment of the new institution. The agricultural school building at Truro was destroyed by fire in March, 1898, and considerable opposition has developed to the establishment of the college at that place. Its location has not yet been decided upon, but there is said to be a tacit understanding that it will be located in Kings County, in the western part of the province. The old agricultural school aimed to provide courses of instruction for farmers' sons, a general science course for the normal-school pupils, and to train agricultural teachers, who would receive \$100 a year additional from the government for teaching elementary agricultural science in the public schools. The work of the new agricultural college is to be confined to courses in agriculture for farmers' sons, and a science school for the teaching of science to the normal-school pupils is to be established at Truro, where the normal school is located. It is expected that the new institution will be more strictly an agricultural school than a college.

EXPERIMENT STATION RECORD,

CONTENTS OF Vol. X, No. II.

	Page
Editorial notes: Statistics of land-grant colleges and agricultural experiment stations, 1898	1001
Recent work in agricultural science	1003
Notes	1099

SUBJECT LIST OF ABSTRACTS.

CHEMISTRY.

Methods for detecting adulterations of bone superphosphates with other super- phosphates, F. Dupont	1003
Estimation of pentoses, A. Grégoire and E. Carpiaux	1003
Contributions on the chemistry of tobacco: II, The determination of the non- volatile organic acids in tobacco, R. Kissling	1004

BOTANY.

Section of seed and plant introduction, O. F. Cook	1012
Experiments in range improvements, J. G. Smith	1005
On the development of the plumule and radicle of rice seed with various quan- tities of water in the germinating medium, T. Yokoi	1006
On absorption of carbohydrates by roots, J. Laurent	1006
Investigations on the carbohydrate reserve material in bulbs and tubers. Leclerc du Sablon	1007

	Page.
The influence of mineral salts on the form and structure of plants, C. Dasselville	1008
Concerning the nitrogen nutrition of plants, L. Richter.....	1011
On the assimilation of nitric nitrogen and ammoniacal nitrogen by higher plants, Mazé	1011
Experiments on the effect of Nitragin and inoculation material upon lupines, W. Edler	1012
Influence of bacterial soil on plant growth, E. Gain.....	1012
FERMENTATION—BACTERIOLOGY.	
Potato as a culture medium, with some notes on a synthesized substitute, E. F. Smith	1014
Which forms of carbohydrates are required by denitrifying organisms for their vital processes? J. Stoklasa	1014
A report on bacteriological investigations of the fermentation of tobacco, J. H. Verhout	1014
Experiments with wine ferments in France.....	1015
On the presence in germinating barley of a ferment capable of dissolving pectin, E. Bourquelot and H. Herissey.....	1015
Concerning some of the less known important functions of micro-organisms, C. Welmer.....	1015
METEOROLOGY—CLIMATOLOGY.	
Monthly Weather Review, Vol. XXVI, Nos. 10-12	1017
Instructions for voluntary observers, W. L. Moore.....	1020
Meteorology of 1897, L. G. Carpenter et al.....	1018
Meteorological record for 1897, New York State Station.....	1020
Meteorological summary for Ohio, 1897, C. A. Patton.....	1019
Report of the meteorologist, A. M. Hildebrandt.....	1020
Relation of meteorology to forestry in Michigan, R. C. Kedzie	1020
Evaporation, L. G. Carpenter et al.....	1019
AIR—WATER—SOILS.	
Investigations concerning the influence of the mechanical working of the soil on its fertility, E. Wolny.....	1020
Report on fertilization, W. Maxwell	1021
Investigations in moor culture, H. Immendorf	1022
Action of lime and calcium carbonate on certain natural humus substances, G. André	1022
Contribution to the solution of the question whether the water content of the soil influences the nitrogen and ash content of the dry matter of plants, J. Wilms and C. von Seelhorst	1023
The forms of phosphoric acid in moor soils, G. Nannes.....	1024
On the direct transformation of ammonia into nitric acid in liquid media, E. Demonssy	1024
Alkali studies, II, E. E. Slosson and B. C. Buffum.....	1025
The alkali of the Yellowstone Valley, M. Whitney and T. H. Means.....	1026
Soil temperatures, L. G. Carpenter et al.....	1030
Soil temperatures, New York State Station	1031
FERTILIZERS.	
Analyses and valuations of fertilizers, L. A. Voorhees and J. P. Street.....	1031
Report of analyses of commercial fertilizers for the fall of 1898, L. L. Van Slyke.....	1033

	Page.
Analyses of fertilizers, C. A. Goessmann.....	1033
Virginia marls, W. B. Ellett and A. T. Eskridge	1032
Investigations on the fertilizing value of carbon bisulphid, E. Wollny.....	1032
Experiments to determine the fertilizer requirements of soils, G. Liebscher et al.....	1033

FIELD CROPS.

Results obtained in 1898 from trial plats of grain, fodder corn, and roots, W. Saunders	1034
The effect of different methods of culture on the yield of mangel-wurzels, E. Wollny	1035
A report of the cultural experiments at the agricultural college at Carlsburg.	1036
Distance experiments with sugar beets and fertilizer tests with potatoes, C. von Seelhorst.....	1036
The composition of sugar beets rich in sugar	1036
The influence of different rates of fertilization on the yields of cultivated plants, E. Wollny	1036
Report of field experiments, 1897-98, A. Danseaux	1036
Test of fertilizers on wheat, D. O. Nourse.....	1037
A contribution to the question of how kainit affects the potato when applied to the preceding crop, O. Lemmermann.....	1038
Researches on the quantities of fertilizing materials necessary in the intensive culture of the potato, A. Girard.....	1038
On the consumption of water in rice fields, I. Inagaki.....	1038

HORTICULTURE.

The Stringfellow root-pruning theory, H. N. Starnes.....	1040
Orchard cultivation, J. T. Stinson.....	1044
Orchard notes, F. S. Earle	1041
Apples in Pennsylvania, G. C. Butz.....	1042
Tests of strawberries, raspberries, blackberries, and grapes, J. Troop.....	1042
Strawberry culture—notes on varieties, L. R. Taft and H. P. Gladden.....	1043
A native white bedding plant, J. C. Arthur	1043

FORESTRY.

A sketch of the original distribution of white pine in the lower peninsula, C. F. Wheeler	1015
The present condition of Michigan forests and stump lands, with suggestions as to their care, F. C. Skeels.....	1015
Forestry legislation, C. D. Smith	1046
Methods of reforesting pine stump lands, W. J. Beal.....	1046

SEEDS—WEEDS.

Seed-testing regulations	1046
On the salt-water method of the selection of seeds, T. Yokoi.....	1047
On the selection of rape seed, C. Kobayashi	1047
On the effect of soaking rice seeds, T. Yokoi	1047
The influence of ether upon the germination of seeds and spores, C. O. Townsend.....	1048
Weeds of cornfields, L. H. Pammel	1048

DISEASES OF PLANTS.

Mycological notes, B. D. Halsted.....	1049, 1050
Cotton rust, F. S. Earle	1051
The potato disease, H. M. Ward	1052

	Page
Diseases of the tomato, P. H. Rolfs.....	1053
The stem-rot diseases of the carnation, F. C. Stewart.....	1054
Penicillium as a wood-destroying fungus, H. M. Ward.....	1055
Nematode worms, G. E. Stone and R. E. Smith.....	1055
Investigations on means for increasing adherence of fungicides, J. Perraud...	1056

ENTOMOLOGY.

Proceedings of the tenth annual meeting of the Association of Economic Entomologists.....	1058
Some miscellaneous results of the work of the Division of Entomology.....	1061
Twentieth report of the State entomologist on the noxious and beneficial insects of the State of Illinois, S. A. Forbes.....	1064
Thirteenth report of the State entomologist on injurious and other insects of the State of New York, 1897, J. A. Lintner.....	1065
Fourteenth report of the State entomologist on injurious and other insects of the State of New York, E. P. Felt.....	1066
Report of the entomologist, A. D. Hopkins.....	1067
Preliminary report upon the insect enemies of tobacco in Florida, A. L. Quaintance.....	1068
The chinch bug, F. M. Webster.....	1069
The periodical cicada, C. L. Marlatt.....	1071
The grapevine flea-beetle, M. V. Slingerland.....	1073
The Hessian fly in the United States, H. Osborn.....	1074
The use of hydrocyanic-acid gas for fumigating greenhouses and cold frames, A. F. Woods and P. H. Dorsett.....	1075

FOODS—ANIMAL PRODUCTION.

EXPERIMENT STATION RECORD.

VOL. X.

No. II.

Educational institutions receiving the benefits of the acts of Congress of July 1, 1862, and August 30, 1890, are now in operation in all the States and Territories except Alaska. The total number of these institutions is 64, of which 61 maintain courses of instruction in agriculture. The aggregate value of the permanent funds and equipment of the land-grant colleges and universities in 1898 is estimated to be as follows: Land-grant fund of 1862, \$10,170,549.99; other land-grant funds, \$1,204,234.44; other permanent funds, \$11,816,258.16; land grant of 1862 still unsold, \$3,838,219.48; farms and grounds owned by the institutions, \$6,046,500.16; buildings, \$15,185,476.95; apparatus, \$1,916,227.85; machinery, \$1,383,137.14; libraries, \$1,634,190.25; miscellaneous equipment, \$1,765,243.19; total, \$53,632,852.25. The income of these institutions in 1898, exclusive of the funds received from the United States for agricultural experiment stations (\$720,000), was as follows: Interest on land grant of 1862, \$645,546.28; interest on other funds, \$578,067.38; United States appropriation under act of 1890, \$1,108,610.38; State appropriation (annual or regular), \$1,827,924.51; State appropriation (occasional), \$533,794.98; tuition fees, \$480,817.32; incidental fees, \$146,458.72; miscellaneous, \$679,130.93; total, \$6,008,379.20. The value of the additions to the permanent endowment and equipment of these institutions in 1898 is estimated as follows: Permanent endowment, \$1,424,277.64; buildings, \$851,481.75; library, \$105,661.11; apparatus, \$132,111.90; machinery, \$123,477.63; miscellaneous, \$167,336.53; total, \$2,796,350.97. The number of persons in the faculties of the colleges of agriculture and mechanic arts were as follows: For preparatory classes, 254; for collegiate and special classes, 1,564; total, 1,722. In the other departments the faculties aggregated 889, making a grand total of 2,611 persons in the faculties of the land-grant institutions. The students in 1898 were as follows: (1) By classes—preparatory, 6,593; freshmen, 6,016; sophomores, 4,202; juniors, 3,216; seniors, 2,506; special, 4,526; post graduate, 878; total, 31,658. (2) By courses—agriculture, 4,181; mechanical engineering, 2,797; civil engineering, 1,504; electrical engineering, 1,698; mining engineering, 554; architecture, 411; household economy, 1,298; veterinary science, 419; military tactics, 8,952. The graduates in 1898 were 2,328, and since the organization of these institutions 34,168. The average age of graduates in 1898 was 22.1 years. The total number of volumes in the libraries was 1,221,226. The total number of acres of land granted to the States under the act of 1862 was 9,559,241, of which 1,241,686 are still unsold.

Agricultural experiment stations are now in operation under the act of Congress of March 2, 1887, in all the States and Territories. Agricultural experiments have been begun in Alaska with the aid of national funds, and an experiment station is in operation in Hawaii under private auspices. In each of the States of Alabama, Connecticut, New Jersey, and New York a separate station is maintained wholly or in part by State funds, and in Louisiana a station for sugar experiments is maintained partly by funds contributed by sugar planters. Excluding the branch stations established in several States, the total number of stations in the United States is 54. Of these, 52 receive the appropriation provided for in the act of Congress above mentioned. The total income of the stations during 1898 was \$1,201,921.17, of which \$720,000 was received from the National Government, the remainder, \$481,921.17, coming from the following sources: State governments, \$341,097.94; individuals and communities, \$177.20; fees for analyses of fertilizers, \$54,977.30; sales of farm products, \$65,356.25; miscellaneous, \$20,312.48. In addition to this, the Office of Experiment Stations had an appropriation of \$35,000 for the past fiscal year, including \$5,000 for the Alaskan investigation. The value of additions to equipment of the stations in 1898 is estimated as follows: Buildings, \$109,851.65; libraries, \$11,700.73; apparatus, \$19,195.43; farm implements, \$10,800.27; live stock, \$13,151.33; miscellaneous, \$11,972.97; total, \$176,469.41.

The stations employ 669 persons in the work of administration and inquiry. The number of officers engaged in the different lines of work is as follows: Directors, 75; chemists, 148; agriculturists, 71; experts in animal husbandry, 10; horticulturists, 77; farm foremen, 29; dairymen, 21; botanists, 50; entomologists, 46; veterinarians, 26; meteorologists, 20; biologists, 11; physicists, 11; geologists, 6; mycologists and bacteriologists, 19; irrigation engineers, 7; in charge of substations, 15; secretaries and treasurers, 23; librarians, 10, and clerks, 46. There are also 21 persons classified under the head of "miscellaneous," including superintendents of gardens, grounds, and buildings, apiarists, herdsmen, etc. Three hundred and five station officers do more or less teaching in the colleges with which the stations are connected.

During 1898 the stations published 406 annual reports and bulletins. Besides regular reports and bulletins, a number of the stations issued press bulletins, which were widely reproduced in the agricultural and county papers. The mailing lists of the stations now aggregate half a million names. Correspondence with farmers steadily increases and calls upon station officers for public addresses at institutes and other meetings of farmers are more numerous each year. The station officers continue to contribute many articles on special topics to agricultural and scientific journals. A number of books on agricultural subjects, written by station officers, have been published during the past year.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

Methods for detecting adulterations of bone superphosphates with other superphosphates, F. DUPONT (*Bul. Assoc. Chim. Sucri. et Distill.*, 16 (1898-99), No. 8, pp. 767-771).—A summary and criticism of the methods submitted in competition for the prize of 1,600 francs offered by the Federation of Italian Agricultural Syndicates. The competitors included 4 Americans, 3 Frenchmen, 2 Italians, 1 Swiss, and 1 Austrian. The prize was awarded to H. Lasne, who submitted a detailed chemical and microscopical method for the purpose. Among those who submitted methods were A. P. Bryant (*E. S. R.*, 8, p. 283), H. A. Huston, and F. Martinotti (*E. S. R.*, 10, p. 219).

Estimation of pentoses, A. GRÉGOIRE and E. CARPLAUX (*Bul. Assoc. Belge Chim.*, 12 (1898), pp. 113-151; *abs. in Analyst*, 24 (1899), Feb., p. 39).—The authors give an account of their investigations on different methods for determining pentoses, including the phenylhydrazin and phloroglucin methods. In the gravimetric phenylhydrazin method they found a small error due to the slight solution of the hydrazone in the wash water. To obviate this they devised a gas gravimetric process in which the nitrogen in the phenylhydrazin is determined before and after the precipitation, and the difference calculated into the amount taken up by the furfural. For the determination of nitrogen in the phenylhydrazin from 4 to 4.5 gm. was dissolved in 250 cc. of water, 25 cc. of the solution mixed with 20 cc. of concentrated hydrochloric acid, boiled for several minutes to remove the air, and introduced while hot into a Schloessing apparatus containing 25 cc. of a 20 per cent solution of copper sulphate and a little hydrochloric acid. The determination was made in the usual way.

For the precipitation of the furfural 81.5 gm. sodium chlorid was dissolved in about 400 cc. of water, 2 drops of acetic acid added and a quantity of furfural not exceeding 0.6 gm. After the addition of an aqueous solution of phenylhydrazin (4 to 4.5 gm. in 250 cc.) the liquid was made up to 500 cc. and shaken for at least an hour. The filtrate was at once mixed with hydrochloric acid, which was found to prevent the decomposition of phenylhydrazin acetate. It was then boiled to expel the air, and 200 cc. containing 20 cc. of hydrochloric acid, was used for determining the nitrogen, in Schloessing's apparatus, this

being deducted from the amount found in the first determination. The result multiplied by the factor 3.429 gave the amount of furfural.

In 7 analyses of furfural by this method the percentages found varied from 99.1 to 102.4, the average being 100.5 per cent.

Contributions on the chemistry of tobacco: II. The determination of the nonvolatile organic acids in tobacco, R. KISSLING (*Chem. Ztg.*, 23 (1899), No. 1, pp. 2-1).—This deals with the method and results of the determination of oxalic, citric, and malic acids in different kinds of tobacco. The results obtained are given below:

Oxalic, citric, and malic acids in different kinds of tobacco.

	Havana.	Brazilian.	Sumatra.	Virginia.	Seed leaf.	Pfalzer.	Macedonia.	Bosnia.
	Percent.	Percent.	Percent.	Percent.	Percent.	Percent.	Percent.	Percent.
Oxalic acid	2.08	3.05	2.50	1.80	0.96	1.74	3.72	2.29
Citric acid	5.32	5.99	6.40	2.81	8.73	5.20	0.55	1.63
Malic acid	3.49	3.56	4.95	6.20	4.72	10.40	3.78	8.08

The averages for these acids are given as follows: Oxalic 2.28, citric 5.75, and malic 5.65 per cent.

Dictionary of industrial chemistry, A. M. VILLON and P. GUICHARD (*Dictionnaire de chimie industrielle. Paris: B. Tignol, 1899, Vol. 2, No. 19*).

A treatise on quantitative chemical analysis by electrolysis, J. RIBAN (*Traité d'analyse chimique quantitative par électrolyse. Paris: Masson et Cie., 1899, pp. VI + 304, figs. 96*).

Methods of analysis adopted by the experiment stations of Belgium and Holland, F. HOLLEMANN (*Landw. Vers. Stat., 51 (1899), No. 4-5, pp. 357-365*).—The methods have been previously noted (E. S. R., 10, p. 304).

Questions which arise in the analysis of potashes, LACOMBE (*Bul. Assoc. Chim. Sucr. et Distill., 16 (1899), No. 9, pp. 894-907*).

On the unreliability of Böttcher's method for determining citrate-soluble phosphoric acid in Thomas slag, M. PASSON (*Ztschr. Angew. Chem., 1899, No. 1, p. 5*).—The author found this method (E. S. R., 10, p. 310) to give results one-half per cent higher than those obtained with the molybdic method. This error is ascribed to the presence of silica in the precipitate.

On the insoluble residue from the treatment of Thomas slag with Wagner's solution, M. PASSON (*Ztschr. Angew. Chem., 1898, No. 21, pp. 489, 490*).—The residue, carefully washed with water, alcohol, and ether was submitted to analysis. It was found that the phosphoric acid was still dissolved to a considerable extent by citrate solutions. The phosphoric acid of the fine meal was more soluble than that of the coarse slag, but when the coarse portion was ground fine, the phosphoric acid was as soluble as in the unsifted meal.

On the determination of phosphorus and sulphur in plants and in their ashes, M. BERTHELOT (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 1, pp. 17-23; abs. in Rev. Sci. [Paris], 4. ser., 11 (1899), No. 2, p. 51*).—The ordinary methods of determining these substances, by cautious incineration or prolonged digestion in concentrated nitric acid, are stated to be very inaccurate. A much more exact method was found to be incineration in oxygen in a calorimeter, the gases produced being conducted through a long column of sodium carbonate heated to low redness to prevent loss by volatilization.

On the presence and determination of chlorin in plants, M. BERTHELOT (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 1, pp. 23-26*).—The method of determining phosphorus and sulphur described above was used successfully in the determination of chlorin.

Testing butter for foreign fats, R. WOLLYN, (*Oesterr. Chem. Ztg.*, 2 (1899), No. 5, pp. 124-126).—A quite general paper on this subject, presented at the Third International Congress of Applied Chemistry, 1898.

The determination of lactic acid, F. ULZER and H. SEIDEL (*Monatsh. Chem.*, 18 (1898), p. 138; *abs. in Ztschr. Analyt. Chem.*, 38 (1899), No. 1, p. 58).

The direct analysis of sugar beets by digestion in water in the cold, J. ZAMARON (*Bul. Assoc. Chim. Sucri. et Distill.*, 16 (1899), No. 9, pp. 885-887; *abs. in Sucri. Ind.*, 53 (1899), No. 15, pp. 449-453).

Determination of mercury in grapes, wine, lees, and marc, L. VIGNON and BARRILLOT (*Compt. Rend. Acad. Sci. Paris*, 128 (1899), No. 10, pp. 613-615).

The determination of mercury in products of vines treated with mercurial solutions, L. VIGNON and J. PERRAUD (*Compt. Rend. Acad. Sci. Paris*, 128 (1899), No. 13, pp. 830-833; *Rev. Sci. [Paris]*, 1. ser., 11 (1899), No. 11, p. 459).

Determination of nitrites in water, D. DE PAEPE (*Bul. Assoc. Belg. Chim.*, 12 (1898), p. 98; *abs. in Jour. Soc. Chem. Ind.*, 17 (1898), No. 9, p. 875).

On the analysis of water for chemical purification, L. VIGNON and MECNIER (*Compt. Rend. Acad. Sci. Paris*, 128 (1899), No. 11, pp. 683-686).—Describes method for the determination of the free and partly combined carbon dioxide and of the amount of sodium carbonate necessary to transform the chlorides and sulphates present.

A contribution to agricultural chemistry—cardamoms, H. B. YARDLEY (*Chem. News*, 79 (1899), No. 2051, p. 122).—An analysis of the ash of cardamom seeds (with husk).

The chemistry of saffras, C. KLEBER (*Amer. Jour. Pharm.*, 11 (1899), No. 1, pp. 27-32; *abs. in Tech. Quart.* 12 (1899), No. 1, *Rev. Chem.*, p. 23).—Principally a study of the essential oils.

The solanin content of potatoes; and a reliable reaction for the detection of the alkaloid, BANES (*Ztschr. Angew. Chem.*, 1899, No. 5, pp. 99, 100; *abs. in Jour. Soc. Chem. Ind.*, 18 (1899), No. 5, p. 301).

On solanin, P. CAZENEUVE and P. BRETEAU (*Compt. Rend. Acad. Sci. Paris*, 128 (1899), No. 14, pp. 887-890).

Sumac and its adulterants, M. O'CALLAGHAN and J. RANDALL (*Jour. Soc. Chem. Ind.*, 18 (1899), No. 2, pp. 105-107).

The chemical balance of an intensive farm, J. ERNOTTE and G. SEMAL (*L'Ing. Agr. Gembloux*, 9 (1899), No. 8, pp. 476-481).

A new form of potash bulb, W. C. ANDERSON (*Jour. Soc. Chem. Ind.*, 18 (1899), No. 2, p. 119, fig. 1).

A serviceable generator for hydrogen sulphid, W. P. BRADLEY (*Amer. Chem. Jour.*, 21 (1899), No. 4, pp. 370-376, fig. 1).

An apparatus for evaporation in vacuo and under pressure, A. GAWALOWSKI (*Ztschr. Analyt. Chem.*, 38 (1899), No. 1, pp. 30, 31, fig. 1).

A sterilization apparatus for the laboratory, J. HAUSSEER (*Bul. Soc. Chim. Paris*, 3. ser., 21 (1889), No. 5, pp. 250-253, fig. 1).

The lighting of laboratories and the heating of apparatus by carburetted air, C. MASSON (*L'Ing. Agr. Gembloux*, 9 (1899), No. 8, pp. 481-483, fig. 1).

BOTANY.

Experiments in range improvements, J. G. SMITH (*U. S. Dept. Agr., Division of Agrostology Circ. S.*, pp. 5, fig. 1).—The general depreciation in the stock ranges of the Southwest and the reasons therefor are pointed out. Experiments have been undertaken by the Division at two points in Texas to determine the most practical and economical way of treating natural pastures in order to again cover them with native

grasses or with better species from other regions. The plan of the experiment is as follows:

Pasture No. 1.—No treatment except to keep stock off until June 1, pasturing the balance of the season.

Pasture No. 2.—Cut with a disk harrow and kept stock off until June 1, pasturing the balance of the season.

Pastures Nos. 3 and 4 (40 acres each).—Grazed alternately, the stock being changed from one pasture to another every 2 weeks, thus allowing the grasses a short period for recovery after each grazing.

Pasture No. 5.—No treatment except pasturing until June 1 and keeping stock off the balance of the season.

Pasture No. 6.—Left as a check, without any treatment whatever except to keep stock off during the first season.

Pasture No. 7.—Dragged with an ordinary straight-toothed harrow and stock kept off during the first season.

Pasture No. 8.—Disked and stock kept off during the first season.

Although sufficient data is not available for definite statements, the outlook for an increase in the quantity of grass on these overstocked pastures is encouraging. During the succeeding seasons experiments will be made as to the practicability of sowing alfalaree, burr clover, Bokhara clover, alfalfa, sorghum, and other wild and cultivated grasses and forage plants directly on the sod without further treatment than to keep the stock off during at least the first year.

It is the expectation to carry on these experiments for at least 3 years, at the end of which time definite results are hoped to be secured which will enable stockmen to decide the best method of restoring their pastures.

On the development of the plumule and radicle of rice seed with various quantities of water in the germinating medium, T. YOKOI (*Imp. Univ. Col. Agr. [Tokyo] Bul., Vol. 3, No. 5, pp. 482-487, pls. 2*).—On account of the practice of covering rice fields with water to facilitate germination, the author has made a study of the effect of such treatment on the development of the plant. Rice was grown in sand cultures to which various amounts of water were given, and the effect on the development of the plumule and radicle was noted. When allowed to germinate under water, the plumule develops 2 or 3 days before the radicle, while when the quantity of water contained in the sand is considerably less than saturation, the radicle develops before the plumule. When the percentage of water falls below 27, germination is retarded, and with it the development of the seedling. It was also observed that the radicle when surrounded with an abundant supply of water bore few or no root hairs. These observations have an important bearing on the development of plants, and it is suggested that in irrigating rice fields after sowing, only sufficient water for the saturation of the soil should be admitted until the seedlings have established themselves by their rootlets.

On absorption of carbohydrates by roots, J. LAURENT (*Compt. Rend. Acad. Sci. Paris, 127 (1898), No. 20, pp. 786, 787*).—In a previous note (*E. S. R., 9, p. 724*) the author has shown that the roots of maize

are capable of absorbing and utilizing glucose and invert sugars. The cultures were made in sterile liquid media and served to show under the conditions of the experiment that maize will grow for several weeks in an atmosphere deprived of carbon dioxide. Check plants cultivated without glucose under bell jars gained little or nothing in dry weight during the experiment. In darkness and the presence of glucose the increase in dry weight of maize plants was considerably less than in the light, although still appreciable. Maize, as is shown, is able not only to reduce sugars but also saccharose, dextrin, and starch. The roots of wheat, maize, and peas are able to invert cane sugar sufficient for their necessities. The digestion of dextrin and starch by the roots of maize takes place slowly, and only very small quantities of glucose can be recognized in the culture; nevertheless these two substances may be taken up in appreciable quantities, two plants of maize having consumed in 34 days about 0.5 gm. of starch.

Following the same system of sterile cultures, the author shows that glucose may be absorbed by the roots of different plants and serve directly for synthesis of starch. Plants of mercury, peas, common groundsel, *tropaeolum*, and sunflower were grown for some time in distilled water in darkness until their starch was used up. Their roots were then placed in a solution of glucose and exposed to sunlight in an atmosphere deprived of carbon dioxide. After 6 hours at a temperature from 20 to 25° C. the leaves were found rich in starch, while the check plants in distilled water did not contain any. Similar results were obtained with ivy, calendula, and round-leaved mallow by simply watering the soil in which the plants were grown with a solution of glucose.

In the different experiments it was observed that the starch first appeared in the cells surrounding the stomata, and in these cells it was last to disappear in the darkness.

Summing up his conclusions, the author states that from his studies there must be two methods of carbon assimilation—one the ordinary chlorophyll function and the other the absorption of certain chemical compounds after their digestion by the roots. This last method is entirely distinct from the carbon nutrition of fungi and plants without chlorophyll.

Investigations on the carbohydrate reserve material in bulbs and tubers, LECLERC DU SABLON (*Rev. Gén. Bot.*, 10 (1898), No. 117, pp. 353-369; 118, pp. 385-403; 119, pp. 447-482; 120, pp. 519-538, figs. 13).—Studies are reported on the carbohydrate reserve material in the bulbs and tubers of *Ophrys aranifera*, tulip, hyacinth, lily, colehiem, potato, *Ranunculus bulbosus*, arum, iris, *Ficaria ranunculoides*, artichokes, dahlia, onion, asphodel, and *Stachys tuberosa*. For the most part the reserve organs studied are biennial. During the first year they form their reserves for utilization during the second year, and between these two periods there is a resting stage.

Among the plants investigated it was found that the carbohydrate

reserve material in the tubers of the potato, rhizomes of arum and iris, and the tubers of colchicum, and *Ranunculus* consists almost entirely of starch. Dextrin and sugar were present, but in very small quantities. In the tubers of *Ophrys*, the bulbs of lily, tulip, and hyacinth the reserve material consists of starch mixed with dextrin, or a mucilaginous substance more or less soluble in water. In the tubers of *Ficaria* the reserve consists of starch, dextrin, and nonreducing sugars. In the dahlia, which may be compared with the tulip bulbs, the starch is replaced by inulin and the dextrin by levulin. In the artichoke inulin, levulin, and nonreducing sugars are present. In the onion and asphodel mixtures of reducing and nonreducing sugars form the greater part of their reserve material.

In the reaction which takes place in the using up of the reserve material by the plant the starch is transformed into dextrin, then into nonreducing sugars, and later into reducing sugars. Dextrin is transformed into nonreducing and reducing sugars. Inulin is reduced similarly to starch, but levulin takes the place of dextrin, and the last form present is levulose and not glucose. The carbohydrate materials are directly or indirectly transformed into reducing sugar or glucose, in which form they are assimilated, the only exception in the material studied being the reserve in *Stachys*. In this galactan is present and seems to be directly assimilable.

The formation of the reserve material is much more complicated, since the action of diastases and the living protoplasm must be considered. It seems impossible to accelerate the formation of reserve material or to increase the proportion of intermediary products. The investigator must be content to establish the presence of compounds in the reserve organs from which the reserve material is formed. As an example, young tulip bulbs contain dextrin and nonreducing sugar. The sugar and afterwards the dextrin diminishes as the starch increases and from this it would be concluded that sugar is transformed into dextrin and dextrin into starch, but this transformation so far has not been reproduced by experiment. In most of the other plants which have starch as reserve material similar observations can be made. The sugars, especially the nonreducing sugars and dextrin, generally precede the formation of starch. On the other hand, in potatoes and arum the young tubers do not contain much sugar or dextrin and here it seems possible that the starch may be formed directly, or it may depend on substances other than sugar. Inulin and levulin are formed apparently in a somewhat similar manner to starch and dextrin. The galactan of *Stachys*, which is directly assimilated, is also directly formed.

The influence of mineral salts on the form and structure of plants, C. DASSONVILLE (*Rev. Gén. Bot.*, 10 (1898), No. 109, pp. 15-25; 110, pp. 59-68; 111, pp. 102-124; 112, pp. 161-170; 113, pp. 193-199; 114, pp. 238-260; 115, pp. 289-304; 116, pp. 335-344; and 117, pp. 370-380,

pls. 10, figs. 5; abs. Bot. Centbl., Beihefte, 8 (1898), No. 1-5, p. 291; Compt. Rend. Acad. Sci. Paris, 126 (1898), No. 11, pp. 856-858; Bot. Ztg., 2. Abt., 57 (1899), No. 1, pp. 51, 55).—The influence of salts on the growth of plants was investigated in a number of ways. Plants were grown in distilled water and in Knop's solution (E. S. R., 8, p. 744), and the external and internal characteristics of each plant compared. In a second series of experiments the effect of single salts was studied in the same way, comparisons being made with plants grown in distilled water and in Knop's solution. The effect of the absence of different salts from the nutrient was also noted. The plants upon which most of the experiments were conducted were seedling lupines, beans, rye, oats, wheat, maize, flax, gourds, hemp, morning glory, castor bean, sunflower, mustard, buckwheat, tomato, and young plants of the potato. For the most part, plants in the Knop solution grew well and flowered, while those grown in distilled water were much smaller and did not flower. The plants in distilled water remained alive as long as those grown in nutrient solutions, and in some cases longer, and the small amount of tissue developed by them was strikingly unlike the same tissues in the other plants in that it was differentiated to a greater degree. Plants in Knop's solution were larger and more vigorous, but there was little differentiation of tissues. There was a lack in the development of cuticular, scleriform, and ligneous tissues when the plant was highly nourished.

The difference in growth in distilled water and Knop solution of a number of plants may be shown. The roots of bean plants grown in the nutrient solution were less lignified, and there was a great increase in vascular tissues as compared with plants grown in distilled water. In the stems the vascular bundles were more numerous. The experiments with oats were similar in their results. The oat leaves in the nutrient solution possessed a greater number of nerves and a greater development of mesophyll. The maize plants grown in distilled water had no root hairs, while those in the Knop solution were abundantly supplied with them, the air spaces were increased, and the vascular bundles were augmented. Similar results were secured for most of the other plants with which the author experimented. In all there was a marked absence of lignification when the plants were grown in nutrient solutions.

In the second part of the paper, in which the action of different salts on the growth of plants is reported, it is stated that magnesium sulphate retards growth at first but later seems essential to the development of lupines, castor beans, and hemp. The retarding effect seems to be principally shown on the roots, the main root of the castor bean being atrophied. Potassium phosphate was found indispensable to the growth of lupines, castor beans, rye, wheat, oats, gourds, and pine. In wheat and oats it favored root growth in proportion to the quantity present. Large amounts tend to prevent lodging in wheat and oats

by inducing the lignification of the central cylinder of the roots and the meristem in the lower part of the stem. Of all the modifications brought about in different plants this is the most important from an agricultural point of view.

Potassium silicate did not prevent the lodging of oats. Its effect seems exerted principally upon the flower parts and leaves of the wheat, the leaves had a peculiar bright green color and were much more hairy. The salt induces the lignification of the peripheral elements toward the top of the stem as well as in certain parts of the leaves.

The action of nitrates was found to differ with different species. These salts were necessary for the growth of pine, although they retarded the root growth. They are equally as essential for the *Ipomoea* although strongly injurious at first. With the lupines the early action of nitrates is advantageous, but later it is prejudicial to their best development. Potassium nitrate is injurious to the growth of wheat, oats, and eggplants in proportion to the quantity used. Calcium nitrate favors the development of tomatoes, while it retards the growth of pines. In soil cultures ammonium nitrate and potassium nitrate were very favorable to the growth of hemp and buckwheat, while sodium nitrate was injurious. It is said that nitrates, without regard to their base, give to leaves a special color which is doubtless due to the nitric acid.

Although the potassium phosphate was found to decrease the tendency of cereals to lodge, this is apparently due to the phosphate, since potash as a base is said to favor cell division, and as a consequence rapid growth, thus retarding lignification and favoring lodging. Sodium was found less active in inducing growth, but it hastens lignification of the lower part of the stem of cereals, preventing lodging. Calcium and magnesium were found to favor the growth of hemp and buckwheat. Experiments with the last two plants, it is claimed, showed the order of efficiency of the acids in the bases used to be nitric, phosphoric, and hydrochloric.

A series of plat experiments with buckwheat and hemp is also reported in which the effect of sodium and potassium chlorids, sodium, potassium, and ammonium nitrates, calcium and magnesium sulphates, potassium phosphate, ferric phosphate, and potassium oxalate on germination, growth, and yield were tested.

Sodium chlorid injured the plants in proportion to the quantity used. Potassium chlorid in proportion of 13.332 gm. per square meter favored germination, while the oxalate was injurious. The potassium chlorid favored growth in the earlier stages, but later the same quantity became detrimental. The optimum quantity at the beginning of growth proved very injurious at the flowering period. Of the nitrates tested, the sodium nitrate had an injurious effect on the growth of the buckwheat, while the others favored it. The sulphates favored growth, and in the earlier stages the influence was proportionate to the amount used.

The potassium phosphate increased growth, while the ferric phosphate had some little influence in increasing growth, but in large quantities it caused a change in the color of the leaves.

The effect of the salts on the dry weight of the plants is shown, and statements made relative to the effect of different quantities of each salt, the optimum quantity for plant growth being sought.

The summary statements in the paper must not be considered as generalizations, but to apply only under the conditions of the experiments.

Concerning the nitrogen nutrition of plants, L. RICHTER (*Landw. Vers. Stat.*, 51 (1898), No. 2-3, pp. 221-241, pl. 1).—The author reports an extensive series of experiments with peas, buckwheat, mustard, and oats to study the effect of continual cropping upon the exhaustion of the soil nitrogen. The pots in the experiment each contained 3,600 gm. sand and 1,200 gm. garden soil, to which were added chemical fertilizers. In one series nitrogen in the form of calcium nitrate was added. Series of sterilized and nonsterilized, inoculated and noninoculated pots were arranged, and the results obtained with each of the three successive crops are shown in tabular form.

Photographic representations are made of average plants of the third crop, from which it appears that only the leguminous plants were able to utilize the free nitrogen of the air. An increase in the dry weight and the nitrogen was noticeable in each succeeding crop of peas, while with the nonleguminous plants there was a loss of each in proportion to the decrease in assimilable nitrogen. There was an increase noticed in the nitrogen in the soil in some cases where nonleguminous plants were grown, which the author does not seem to explain. This increase was slight for the first crop and increased with successive seedings. The plants did not seem able to utilize the nitrogen so stored. Where combined nitrogen in the form of calcium nitrate was added to the pots, in every case a loss was noted in the nitrogen balance at the end of the experiment.

The accuracy of the experiments which showed a loss of nitrogen, where that substance was given the plants in an assimilable form, was further tested the succeeding season in experiments with oats and similar results obtained. Pots containing no other plants were allowed to become covered with various algae, and the nitrogen balance showed gains whether the experiment was conducted in light or darkness. Check pots without plants showed losses in every case.

On the assimilation of nitric nitrogen and ammoniacal nitrogen by higher plants, MAZÉ (*Compt. Rend. Acad. Sci. Paris*, 127 (1898), No. 24, pp. 1031-1033).—The author conducted a series of experiments on the germination of peas, maize, and vetches grown in nutritive solutions to which were added various amounts of nitrate of soda or sulphate of ammonia, to ascertain whether these plants possess the ability of assimilating ammoniacal nitrogen. A tabular report is given of the experiments with maize in which it is shown that ammonia can be absorbed and assimilated by the higher plants.

Experiments on the effect of Nitragin and inoculation material upon lupines, W. EDLER (*Fühling's Landw. Ztg.*, 48 (1899), No. 1, pp. 22, 23).—A report is given of pot experiments with lupines in which soil inoculation and Nitragin inoculation were compared with each other and with plants grown in pots which did not receive any inoculating material. Fifteen pots were filled with a light sandy soil free from lime, and all were equally fertilized with phosphoric acid and potash. Five pots were inoculated with Nitragin, 5 with soil-inoculating material from Dr. Salfeld, and the others remained as checks. The yield of the several pots is given, from which it appears that as compared with the yield of grain from the untreated pots the yield of grain from the pots which received Nitragin was 38.44 per cent greater and from those receiving the soil-inoculation material 106.51 per cent greater. The yield of plants was increased 12.17 and 42.86 per cent respectively.

The same line of experiments was undertaken in the open field on clay soil. In this experiment the rows of yellow, black, white, and blue lupines were grown across the field, the different rows receiving the different inoculating materials. Some differences were noted in growth, but the experiment only tended to more firmly establish the author in the opinion that when the mechanical and chemical conditions of the soil are not suited to the growth of lupines, no addition of lupine-inoculation material will materially increase the growth of those plants.

Influence of bacterial soil on plant growth, E. GAIN (*Rev. Gén. Bot.*, 11 (1899), No. 121, pp. 18-28).—After briefly reviewing the general subject of relation of soil bacteria to plant growth, the author gives in some detail a report of experiments conducted to test the efficiency of Alinit in promoting the growth of cereal and allied plants. The first series was conducted with flax, the plants being grown in pots containing garden soil. The results in these experiments showed that plant growth was increased in all those pots which had been inoculated with Alinit.

Plat experiments were conducted in a similar manner with buckwheat and flax. The buckwheat was grown in garden soil and the yield from the inoculated plats exceeded that of those receiving no inoculation material, the gain in seed being 7.5 per cent and in plant 12 per cent. The plat experiments with flax which were conducted in a siliceous calcareous soil showed similar effect due to the inoculation, the proportional gains being 11.4 per cent for the total weight of the plants and 9.3 per cent for the seed.

The author states that under the conditions of these experiments it seems that Alinit exercises a very favorable effect on the total development of plants and also upon the amount of seed matured.

Section of seed and plant introduction, O. F. COOK (*U. S. Dept. Agr., Division of Botany Circ.* 16, pp. 6).—The recent transfer of this section to the Division of Botany, together with a change in the personnel of the Office, has made it desirable to supplement some of the details of the plans under which the work of plant intro-

duction is to be continued. The general purpose and methods of plant introduction have been set forth in Bulletin 21 of the Division of Forestry (E. S. R., 10, p. 927).

Meadows on moor soils of the royal forest domain Zehdenick, L. WITTMACK (*Landw. Jahrb.*, 27 (1898), No. 3-4, pp. 17-331).—Fertilizer and culture tests were made and the growth of the different grasses and other meadow plants observed. The results obtained in 1896 and 1897 are given in tables and discussed. Different species of grasses are briefly noted.

Saltbush, J. VILBOUCHEVITCH (*Ann. Sci. Agron.*, 1898, II, No. 2, pp. 268-271).—A note on *Atriplex semibaccatum*.

Concerning the genus Phyllactinia, E. PAULA (*Ber. Deut. Bot. Gesell.*, 17 (1899), No. 2, pp. 64-72, pl. 1).—*Phyllactinia berberidis* n. sp. is described and studies are reported upon the haustoria of the genus.

Influence of light on the development of some fungi, F. GRAENITZ (*Univ. Diss.*, Leipzig, 1898, pp. 74; *abs. in Bot. Ztg.*, 2. Abt., 57 (1899), No. 7, pp. 97-99).—Studies are reported on *Pilobus microsporus* and *Coprinus stercorarius*.

Influence of light upon the respiration of the lower fungi, R. KOLKOWITZ (*Jahrb. Wiss. Bot.*, 33 (1899), No. 1, pp. 128-165, pls. 2).—The effect of light upon molds and bacteria was investigated.

Specific characters of Endomyces albicans, P. VUILLEMIN (*Compt. Rend. Acad. Sci. Paris*, 127 (1898), No. 1, pp. 630-633).—The author claims the discovery of ascospores in this fungus and groups under the above name all the forms of *Oidium albicans*, etc.

Contributions to the biology of pollen, B. LIDFORSS (*Jahrb. Wiss. Bot.*, 33 (1899), No. 2, pp. 232-312).

On the absorption of halogen salts of potassium by plants, E. DEMOSSY (*Compt. Rend. Acad. Sci. Paris*, 127 (1898), No. 20, pp. 771-774).—The author shows that colza is able to absorb through its roots considerable chlorine and bromine from the potassium salts containing them. A marked difference is noted between those plants which are able to absorb iodine and those not so constructed.

On contact irritability, A. J. EWART (*Ann. Jard. Bot. Buitenzorg.*, 15 (1898), No. 1, pp. 187-242, pls. 2, figs. 5).

A contribution to the knowledge of the anatomy and physiology of water-secreting organs (*Beiträge zur anatomischen und physiologischen Kenntniss Wasser secernirender Organe*. Stuttgart: M. von Minden, 1899, pp. 76, pls. 7).

On the growth of root hairs and rhizoids, C. SOKOŁOWA (*Bul. Soc. Imp. Nat. Moscow*, 1897, pp. 167-277, figs. 3; *abs. in Bot. Centralbl.*, 77 (1899), No. 8, pp. 274-276).

Experiments with Alinit, J. STOKLASA (*Deut. Landw. Presse*, 26 (1899), No. 2, p. 13).—The author defends his position relative to the efficiency of Alinit in aiding cereals to acquire free atmospheric nitrogen. The source through which the bacteria are said to act are the carbohydrates in the soil, the proteid material in the bacteria readily uniting with the carbohydrates and becoming available to the plant.

Field experiments with Nitragin, O. BURCHARD (*Landw. Wechnbl. Schleswig-Holstein*, 49 (1899), No. 12, pp. 300, 301).—Reports the advantageous employment of Nitragin both as a soil and seed inoculating material for *Vicia sativa dura* when grown with oats. Gains from 25 to 124 per cent are reported.

Light a factor in sugar production, H. A. WEBER (*Jour. Amer. Chem. Soc.*, 21 (1899), No. 1, pp. 53-59).—Data collected from the history of beet and sorghum culture in the United States are reported to show that the sugar content of the plant is dependent upon the amount of direct sunlight received, and hence that this factor should be taken into consideration in determining the climatic conditions most favorable for beet growing.

Influence of the mode of nutrition on the evolution of plants, P. A. DANGEARD (*Botaniste*, 6. ser., 1898, No. 1, pp. 1-63).—The origin of the differentiation between animals and plants is said to be a difference in the mode of nutrition.

Crossbreeding wheat, L. BROEKEMA (*Organ Ver. Oudler. Rijks. Landbouwschool*, 11 (1899), No. 128, pp. 34-37, pls. 3).—A description of the methods and results of crossing several varieties of Dutch wheat with square-head wheat.

FERMENTATION—BACTERIOLOGY.

Potato as a culture medium, with some notes on a synthesized substitute, E. F. SMITH (*Proc. Amer. Assoc. Adv. Sci.*, 17 (1898), pp. 111, 112).—After discussing some of the advantages and disadvantages of potato as a substratum for the growth of fungi and bacteria, the author states that he considers it a very useful substance which should not be discarded. He further describes a synthesized medium which he has found free from many of the objections urged against the potato, while possessing most of its good qualities. It consists of potato starch combined with a modified Uschinsky solution. The methods for preparation of this medium, which the author has designated as "nutrient starch jelly," are fully given. It is stated that many organisms which previously made only very feeble growth, in this medium grow exceedingly well. This medium possesses excellent keeping qualities and is well adapted to the long-continued growth of many organisms, both fungi and bacteria, and is said to be particularly valuable for studying the diastatic action of various bacteria, some of which grow luxuriantly and convert starch into sugar very rapidly, while others make very feeble growth, being able to convert starch with the greatest difficulty.

Which forms of carbohydrates are required by denitrifying organisms for their vital processes? J. STOKLASA (*Ztschr. Landw. Versuchw. Oesterr.*, 1898, p. 371; *abs. in Chem. Ztg.*, 22 (1898), No. 99, *Repert.*, p. 315).—The author's experiments indicate that xylan, which with other furfuroids occurs abundantly in straw and manure, when hydrolyzed to xylose furnishes the most natural and favorable carbohydrate food for denitrifying organisms. Arabinose is not so well suited to these organisms as xylose. The author made experiments with different carbohydrates in vegetation pots inoculated with *Bacillus denitrificans*. On all pots receiving glucose the yield of oats was normal, while on those receiving xylose the yield was almost a fourth less than in case of pots which had received nitrate of soda and superphosphate. The results on the pots to which arabinose had been applied were practically the same as with those receiving glucose.

Very different results were obtained in experiments with organisms which produce ammonia in the soil. Soils which were inoculated with *Bacillus megatherium* and *B. mycoides* in the presence of nitrates and xylose gave a higher yield of oats than those which had not been so inoculated. The author suggests that this was due to the reduction of the nitrate to ammonia and the thereby increased capacity of the soil for fixing the free nitrogen of the air. The fact that soils rich in furfuroids, especially xylan, contain only traces of nitrates is believed by the author to be due to biochemical action in the soil which quickly reduces the nitrates to ammonia. There is a large number of organisms which reduce nitrates and nitrites to ammonia.

A report on bacteriological investigations of the fermentation of tobacco, J. H. VERHOUT (*Teysmannia*, 9 (1898), No. 2-3, pp. 118-144; *abs. in Centbl. Bakt. u. Par.*, 2. Abt., 4 (1898), No. 20, pp. 778, 779).—The author gives a preliminary report on his investigations of the

micro-organisms of tobacco fermentation. Since tobacco is said to be fermented at temperatures ranging from 50 to 60° C., the investigation was confined to organisms living at this temperature. By means of agar plates cultures were made from fermenting leaves and at about 50° temperature colonies were developed. These were principally of a single species; although others were present, they were not constant. The species isolated from the fermenting tobacco leaves is a bacillus of the *subtilis* group and is spore-forming. It is 2.4 μ in length and 0.5 μ in diameter. It grows readily upon agar, nutrient gelatin, liquefying the latter, and in bouillon and tobacco decoction. Its optimum temperature for growth was about 50°, although it remained living at room temperatures. Upon proteid media it forms ammonia. The investigations are to be continued and the bacterial flora of tobacco leaves before and during fermentation fully studied.

Experiments with wine ferments in France (*Gard. Chron.*, 3. ser., 23 (1898), No. 610, pp. 171-176).—The use of wine ferments by the wine growers of France has been a subject of considerable earnest investigation, and it is asserted that the quality of many wines can be improved by the use of the proper ferments. Brief quotations are given from consular and other publications showing the method of employing the ferments. The directions for preparing the ferments are given, and it is stated that 1 liter of select ferment is used with the juice of from 40 to 50 lbs. of grapes for every 1,600 gal. of must. If properly made, the yeast ferments and is ready for use in 50 to 60 hours after beginning the preparation.

On the presence in germinating barley of a ferment capable of dissolving pectin, E. BOURQUELOT and H. HERISSEY (*Compt. Rend. Acad. Sci. Paris*, 127 (1898), No. 3, pp. 191-191).—The authors report the presence in germinating barley of a diastase, which they have separated by drying the germinating barley at a temperature of from 30° to 35° C. The barley is then ground and macerated for 12 hours in chloroform water, after which it is allowed to settle, removed, filtered, and precipitated with alcohol. The precipitate is collected on a filter, rapidly washed with alcohol and afterwards with ether, and finally dried in a vacuum. Numerous experiments are reported in which this substance was shown to reduce pectin, and the authors state that on account of the lack of information concerning soluble ferments no positive demonstration can be made, yet it is believed a tenable hypothesis that germinating barley contains a diastase somewhat similar to amylose and trehalose, which is capable of reducing the pectin found in gentians.

Concerning some of the less known important functions of micro-organisms, C. WEHMER (*Chem. Ztg.*, 22 (1898), No. 103, pp. 1079-1082).—After briefly reviewing some of the more common forms of fermentation brought about by bacteria and fungi, the author enumerates a number of the less common ones, briefly describing the processes taking place. Among those mentioned are Maercker's acid method

of starch manufacture, Völker's method of starch making, the purification of boneblack in sugar refining, tannin fermentation, the fermentation of opium, the fermentation of beans when prepared somewhat like sauerkraut, the bacterial purification of city sewage, the micro-organisms present in white-lead manufacture, and the fermentations which take place in the manufacture of various dyes and coloring stuffs.

Report of the agricultural bacteriological laboratory at St. Petersburg for 1897. A. THEOKTISTOV (*Rep. in Selsk. Khoz. i Lyesor.*, 190 (1898), No. 8, pp. 325-353).—The scientific activity of the laboratory was devoted to the following investigations: (1) Scientific investigations on the biology and classification of mice-killing bacteria; (2) investigation on the influence of metals on bacterial cultures; (3) investigations on sterilizing nutritive media; (4) work in pathological anatomy; (5) investigation of the conditions of the progressive decrease of the virulence of the bacterial cultures; (6) determination of the absolute virulence of various mice-killing microbes; (7) investigation on chicken cholera, and (8) investigation on new nutritive media.—P. FIREMAN.

Some little-used culture media which have proved valuable for the differentiation of species. E. F. SMITH (*Proc. Amer. Assoc. Adv. Sci.*, 47 (1898), pp. 412, 413).—The author recommends especially the following media for differentiation of various species of organisms: Uchinsky's solution; tubes of standard nutrient agar with addition of 10, 20, and 30 per cent of grape sugar; the same with 10, 20, and 30 per cent of cane sugar; nutrient starch jelly with and without various sugars, alcohols, etc.; cylinders of cocoanut flesh in distilled water; cylinders of white or yellow turnips in distilled water; cylinders of carrot in distilled water; cylinders of white sugar beet in distilled water; potato cylinders standing in several cubic centimeters of distilled water (for prolonged growth); the extension of tests with fermentation tubes so as to include also, in addition to the three sugars in common use—viz. grape, cane, and milk—the following substances: Fructose, galactose, maltose, dextrin, mannite, and glycerin.

The mineral constituents of the tubercle bacilli. E. A. DE SCHWEINITZ and M. DORSET (*Jour. Amer. Chem. Soc.*, 20 (1898), No. 8, pp. 618-620).—Analysis of the ash, with comments.

Bacillus luteus sporogenes. R. F. W. SMITH and J. L. BAKER (*Centbl. Bakt. u. Par.*, 2. Abt., 4 (1898), No. 21, pp. 788, 789, figs. 2; *abs. in Jour. Roy. Micros. Soc.* [London], 1899, No. 1, p. 72).—This bacillus has been separated from 2 different samples of beet sugar. It is a long, endosporegenous bacillus, growing with great rapidity in all the ordinary artificial nutrient media, with the formation of a yellow pigment.

On the mode of action of Bacillus subtilis in the phenomena of denitrification. A. FICHTENHOLZ (*Compt. Rend. Acad. Sci. Paris*, 128 (1899), No. 7, pp. 442-445).—It was found that in presence of air at a temperature of 38 to 39° *Bacillus subtilis* developed in an artificial solution which contained nitrogen only in the nitric form. Under these conditions ammoniacal fermentation takes place, the quantity of ammonia formed varying with the different phases of fermentation. When the maximum was reached the evolution began to decline.

Vinegar bacteria. W. HENNEBERG (*Ztschr. Spiritusind.*, 21 (1898), No. 20, pp. 180, 181; *abs. in Jour. Soc. Chem. Ind.*, 17 (1898), No. 7, p. 684).

The micro-organisms of spoiled wine. F. BORDAS, JOULIN, and RACZKOWSKI (*Compt. Rend. Acad. Sci. Paris*, 126 (1898), No. 20, pp. 1443-1446).—The authors describe a second bacillus which they have isolated from spoiled wine. It is associated with *Bacillus roseus vini*. It is filamentous in form and exercises a marked action on tartaric acid. The authors have made cultures of the organism and compare its action on various culture media with the action of *B. roseus vini*.

Concerning the ferments of wine diseases. J. LABORDE (*Compt. Rend. Acad. Sci. Paris*, 126 (1898), No. 17, pp. 1223-1226).—A preliminary report is given of a study by the author of the organisms found in moldy or bitter wine aside from the yeasts and species of *Mycoderma* found in new wines.

Biological investigations of Tibi, L. LUTZ (*Bul. Soc. Mycol. France*, 15 (1899), No. 1, pp. 68-72).—An account is given of this substance, which is of the nature of kephir. It is said to be used in Mexico in the preparation of a beverage by the fermentation of an *Opuntia*.

Study on ammoniacal fermentation and on the ferments of urea, P. MIQUEL (*Étude sur la fermentation ammoniacale et sur les ferments de l'urée*. Paris: Carré et Naud, 1898, pp. 325, pls. 3, figs. 7).

Lactic acid in fruit and grape wines, H. MÜLLER-THURGAU (*Centbl. Bakt. u. Par.*, 2. Abt., 4 (1898), No. 23, pp. 849-854).—The presence of lactic acid in many of these wines is pointed out, the way in which the content is increased through fermentation is shown, and directions are given whereby much of this undesirable fermentation may be prevented.

Contributions to the biology of wine yeasts, J. A. CORDIER (*Compt. Rend. Acad. Sci. Paris*, 127 (1898), No. 17, pp. 628-630).—The author claims that in France the air is the principal agent of distribution of *Saccharomyces* and other wine ferments, and not insects, as claimed by Berlese, Gigliolo, and others (*E. S. R.*, 10, p. 123).

On the natural dissemination of wine yeasts, L. BOUTROUX (*Compt. Rend. Acad. Sci. Paris*, 127 (1898), No. 24, pp. 1053-1056).

A contribution to the knowledge of the life history of *Saccharomyces guttulatus*, A. WILHELMI (*Centbl. Bakt. u. Par.*, 2. Abt., 4 (1898), No. 9, pp. 353-361; 10, pp. 412-417, figs. 3).—Studies are given of this parasite taken from the stomach and intestines of sheep.

Some recent observations on *Saccharomyces guttulatus*, L. BUSCAGLIONI and O. CASAGRANDI (*Malpighia*, 12 (1898), No. 1-2, pp. 59-75, pl. 1).

Proteolytic enzymes in the plant world, C. FERMI and BUSCAGLIONI (*Centbl. Bakt. u. Par.*, 2. Abt., 5 (1899), No. 1, pp. 24-27; 2, pp. 63-66; 3, pp. 91-95; 4, pp. 125-134; 5, pp. 145-158).

On the chemistry of the action of enzymes and bacterial substances, N. SACHAROFF (*Centbl. Bakt. u. Par.*, 1. Abt., 24 (1898), No. 18-19, pp. 661-665).

Diastatic substances from fungus growths, J. TAKAMINE (*Jour. Soc. Chem. Ind.*, 17 (1898), No. 2, pp. 118-120).

Simple quantitative determination of diastatic power, J. TAKAMINE (*Jour. Soc. Chem. Ind.*, 17 (1898), No. 5, pp. 437, 438).

Researches on diastase and barley malt, SEYFFERT (*La Bière*, 6, No. 5, pp. 68-73; *abs. in Jour. Soc. Chem. Ind.*, 17 (1898), No. 7, pp. 681, 682).

Notes on taka diastase, W. E. STONE and H. E. WRIGHT (*Jour. Amer. Chem. Soc.*, 20 (1898), No. 3, pp. 639-647).—This paper presents the results of some observations upon the action of taka diastase upon starch as compared with the ordinary diastase of malt. The use of taka diastase as an analytical reagent in the determination of starch was also tested, but under the conditions employed it was not found to be adapted to this purpose.

Fermentation without live cells, KATHERINE E. GOLDEN and C. G. FERRIS (*Proc. Amer. Assoc. Adv. Sci.*, 27 (1898), p. 417).—The authors summarize the rather extensive and contradictory literature beginning with that of Büchner in 1897, who claims to have induced active fermentation of various sugars with a sterile extract obtained from dried yeast by filtration through a Berkefeld filter. Büchner's method was followed in the preparation of the extract and although the experiments were repeated three times at temperatures of 37.5° C., as well as at room temperatures, the results were negative in every case. The experiments were then repeated with another compressed yeast, with also negative results.

METEOROLOGY—CLIMATOLOGY.

Monthly Weather Review (*U. S. Dept. Agr., Weather Bureau, Monthly Weather Review*, 26 (1898), No. 10, pp. 439-492, charts 11; 11, pp. 493-525, charts 12; 12, pp. 527-591, charts 12).—In addition to the

usual reports on forecasts and warnings and on weather and crop conditions, and meteorological tables and charts, No. 10 contains special contributions on A record of some kite experiments, by W. A. Eddy; The effect of proximity to the sea on thunderstorm periods, by H. D. Stearns; Removal of Weather Bureau office in New York City, by A. J. Henry; Hot summers and cold winters at Washington, D. C., by F. Gillam; and In memory of Prof. William Ferrel, by P. Connor; and notes by the editor on American climatological publications, notes from the voyage of La Pérouse, lightning on wire fences, and the utilization of fog.

No. 12 contains special contributions on The thunderstorm of September 17-18, 1895, Local atmospheric disturbances, and Are our winters changing? by A. J. Henry; Meteorological observations near Circle City, Alaska, by J. O. Holt; What a weather observer should know, by N. R. Taylor; The San Diego waterspout, by F. A. Carpenter; The weather and storms of Malta during October, 1898, by J. H. Grout; Aneroid barometers, by C. Chree: Civil-service examinations for observers in the United States Weather Bureau, by H. H. Kimball; and Climate and crop report, season of 1898, Alaska section, by H. L. Ball; and notes by the editor on reduction to standard gravity, the practical side of Weather Bureau work, the chemical thermoscope, kite work in Madeira, origin of tornadoes, meteorology in France, the climate of Athens, astronomy for the meteorologist, electrical districts, origin of the word "blizzard," seismic noises, mirobias and seiches, a new elementary meteorology, the Royal Meteorological Society, Civil-service examinations for assistants, St. Elmo's fire, ball lightning, cloud phenomena at sunrise and sunset, distant thunder, a new style of aneroid, low pressures and tidal waves, floating spider webs, the barograph on ships, weights and measures in Porto Rico, the waterspout of September 29, a crude hygrometer, the Weather Bureau and the universities and colleges, Chinook at Havre, Montana, northers in the Caribbean Sea and the Gulf of Mexico, recent earthquakes, the moon and the weather, unequal distribution of snow, recent meteors, and optical phenomena.

Meteorology of 1897, L. G. CARPENTER ET AL. (*Colorado Sta. Bul.* 49, pp. 3-55, 66-70, figs. 17).—This bulletin gives descriptions (with illustrations) of various instruments used in meteorological observations and tabulated summaries of daily observations on temperature, barometric pressure, precipitation, humidity, radiation, sunshine, direction and movement of wind, etc., at Fort Collins during each month of 1897, with monthly summaries of observations (especially temperature and precipitation) at Rockyford, Cheyenne Wells, Estes Park (at base of Longs Peak, elevation 9,000 ft.), Pinkhampton (elevation 8,400 ft.), and Gleneyre (near head of Laramie River, elevation 8,000 ft.). The monthly precipitation is reported by voluntary observers from 4 additional points in the watershed of the Cache a la Poudre River. "These stations have been selected in most cases for the purpose of obtaining a record of the precipitation in the mountains which form the watershed of the adjacent rivers. As the Cache a la Poudre River has been

the subject of investigations for a number of years and records have been maintained of its flow, it has been desired to study the amount and distribution of the precipitation on its watershed."

The characteristics of the Colorado climate are briefly discussed as follows:

"The great variation in altitude in the State, ranging from less than 4,000 ft. at the eastern border to over 11,000 ft. at the summit of numerous peaks, causes a change in climate greater than between New Orleans and Winnipeg, and while Colorado east of the mountains has a mean temperature the same as New York, the temperature of the high peaks is lower than that of Spitzbergen. . . . Still, cultivated and irrigated Colorado is of relatively small range in elevation . . .

"Among the general characteristics of Colorado are: The small rainfall—from one-half to one-third of that east of the Mississippi . . . ; greater range of temperature; a large percentage of sunshine, of great intensity, which, as well as the great range, is a consequence of the great dryness and rarity of the air.

"One of the marked features is the presence of warm westerly winds known as Chinooks, a type present in mountainous countries under various names. While cold waves are not absent, the intensity is less than in the Mississippi Valley States. The conditions which result in blizzards of great intensity in these States cause westerly winds with us and some of the most pleasant weather of winter."

Meteorological summary for Ohio, 1897, C. A. PATTON (*Ohio Sta. Bul. 95, pp. 327-342*).—Notes on the weather and tabulated daily and monthly summaries of observations at the station on temperature, precipitation, cloudiness, direction of the wind, etc., are given; and for comparison similar data for previous years and for other parts of the State. The following is a summary of results:

Summary of meteorological observations in Ohio.

	For the experiment station.		For the State.	
	1897.	For 10 years.	1897.	For 15 years.
Temperature (° F.):				
Mean	49.4	48.9	50.6	50.88
Highest	(July 4-5) 96	(Aug. 8, 1891) 99	(July 4) 113	(July 4, 1897) 113
Lowest	(Jan. 26) -18	(Jan. 29, '92) -20	(Jan. 26) -27	(Jan. 25, '84) -34
Range	79	99.7	140	147
Mean daily range.	21.5	20.3		
Greatest daily range				
Least daily range	(Oct. 5) 49	(Oct. 6, 1895) 55	(Sept. 25-26) 67	(Sept. 25-26, '97) 67
Clear days	124	119	130	118.3
Fair days	123	124	119	123.3

Days rain fell	128	125	110	124.7
Rainfall (in.):				
Total	36.16	38.94	38.54	37.98
Greatest monthly	(Nov.) 5.76	(July, 1896) 8.05		
Least monthly...	(Sept.) 0.29	(Sept., 1897) 0.29		
Mean yearly			38.54	37.98
Prevailing direction of wind	NW.	SSW.	SW.	SW.

Evaporation, L. G. CARPENTER ET AL. (*Colorado Sta. Bul. 49, pp. 64-66, fig. 1*).—A record is given of continued observations on a standard evaporation tank.

"Observations with the hook gage are made twice per day from April to September, gage reading to $\frac{1}{1000}$ of a foot. At the same time the temperature of the water surface is observed twice per day at the maximum and minimum temperatures. During September and October the reading is made once daily. During the winter months ice forms, and the observation is made at the beginning of each month.

"It is found that the evaporation runs from 1 to 2 in. per month during the winter. The evaporation during the night is practically as rapid as during the day.

"An attempt was made to obtain a formula from the observations of 1889 and with enough success to compute the evaporation in 1890 from May to October with a difference of less than half an inch. The formula was as follows:

$$E = .39 (T - t) (1 + .02W).$$

"E represents the evaporation in inches in 24 hours.

"T is the vapor tension corresponding to the temperature of the surface of the water.

"t is the vapor tension corresponding to the temperature of the dew-point at that time.

"W represents the number of miles of wind in the 24 hours.

"Observations have since been made to obtain a more perfect formula, but are not yet reduced."

Elementary treatise on meteorology, A. ANGOT (*Traité élémentaire de météorologie*. Paris: Gauthier-Villars, 1899, pp. VI+412; rev. in *Nature*, 59 (1899), No. 1535, pp. 505, 506).

Instructions for voluntary observers, W. L. MOORE (*U. S. Dept. Agr., Weather Bureau Doc. 184*, pp. 23, figs. 9).—This contains brief instructions for the guidance of voluntary observers in taking and recording observations, more especially of temperature and rainfall.

Meteorological record for 1897 (*New York State Sta. Rpt. 1897*, pp. 619-627).—Tabulated daily and monthly summaries of observations on temperature and monthly summaries of observations on precipitation for the period from 1882 to 1897.

Report of the meteorologist, A. M. HILDEBRANDT (*Texas Sta. Rpt. 1898*, pp. 1134-1136, charts 5).—Tabulated monthly summaries of observations at the station on temperature (1897) and precipitation (1891-1897). Charts show graphically the daily and mean annual rainfall for 1891 to 1897.

The rainfall of the globe, W. ULE (*Rev. Sci. [Paris]*, 4. ser., 11 (1899), No. 13, p. 412).—The mean rainfall of the different grand divisions of the earth is given and discussed.

Extraordinary hailstorms, G. DE ROCQUEGNY-ADANSON (*Rev. Sci. Bourbonnais*, 12 (1899), No. 133, pp. 62-67).—Brief accounts are given of some of the more important hailstorms from 1776 to date.

Sun spots and weather, A. B. MACDOWALL (*Nature*, 59 (1899), No. 1533, p. 462, figs. 2).—A comparison of the number of warm and dry months since 1841 with sun spots.

Relation of meteorology to forestry in Michigan, R. C. KEDZIE (*Michigan Sta. Bul. 163*, pp. 18-31).—After stating the relation of meteorology to forestry and forest growth, relation of soil to moisture, etc., abstracts are given of the meteorological observations covering a period of 34 years, from 1864 to 1897.

AIR—WATER—SOILS.

Investigations concerning the influence of the mechanical working of the soil on its fertility, E. WOLLNY (*Forsch. Agr. Phys. [Wollny]*, 20 (1898), No. 3, pp. 231-289).—Results of previous work in this line have been published heretofore (E. S. R., 7, p. 569). In this article the purpose of the experiments is explained and the results are given in tabular form and discussed at some length. The results obtained by other investigators are cited. The subjects discussed are the mechanical condition of the soil as affected by stirring, the frequency and time of cultivation, the stirring of the surface soil, the use of the land roller, and bed and level culture. Various crops were grown in connection with the different tests. It was found that all crops grown gave better

returns on soils kept in a crumbly condition than on soils reduced to a powder-like fineness, and that the action of fertilizers was also much more evident on the former than on the latter soils. The author recommends fall plowing for land which is to be planted in the spring. It is shown that stirring or hoeing the surface is beneficial when the soil has been packed by rains and that the practice is detrimental during drought when the soil is already in a good mechanical condition. The results of tests show that rolling the land favored a uniform sprouting of the seed, but in general the yield of the rolled plats was smaller than on the plats which had not been rolled. Packing the surface soil by means of a roller was detrimental to plant growth when the soil was not subsequently stirred, but cultivating the soil after rolling precluded any bad effects from this source.

A comparison of bed and level culture gave the following results: The yields of plants on bedded plats was greatest at the ridges and smallest at the furrows: the south side of beds gave the best results, followed by the east, west, and north sides in the order mentioned; the south side of beds running east and west produced larger yields than the north side when moisture conditions were favorable, but during dry seasons the north sides gave the best returns. In general the results were in favor of level culture.

Report on fertilization, W. MAXWELL (*Rpts. Hawaiian Expt. Sta., 1898, pp. 1-11*).—This article discusses the fertilizing constituents of upland and lowland Hawaiian soils soluble in hydrochloric acid, water, and aspartic acid (E. S. R., 10, p. 531); the fertilizing constituents removed from the soil by the sugar-cane crop; the absorptive power of soils for different fertilizing chemicals and the influence of the latter upon the lime content of the soils.

Of 227 gm. of nitrate of soda applied to the soil in a lysimeter, water applied after 48 hours removed 180.3 gm. Of like amounts of potash and phosphoric acid, water removed 43.6 and 3.2 gm., respectively. In a second experiment, of 200 gm. nitrate of soda applied, water removed as nitrate 72.56 gm.; of 200 gm. of sulphate of ammonia applied, water removed 3.08 gm. as nitrate and 0.44 gm. as ammonia.

“In connection with the lysimeter observations, tests were made in order to note the action of the different acids in applied fertilizers upon the lime in soils. The acids used were nitric acid (as nitrate of soda), hydrochloric acid (as chlorid of potash), and sulphuric acid (as sulphates of ammonia and potash). These several salts were applied and 48 hours later the rows of cane, growing over the lysimeter drains, were irrigated, 102 gal. being applied to each row, of which 33 gal. leached out, this drainage being analyzed—

Analyses of drainage water from soil receiving different fertilizing chemicals.

Drain.	Acid applied.	Acid lost. Lime lost.	
		Gm.	Gm.
No. 1.....	No acid.....		1.72
No. 2.....	Nitrate of soda.....	36.28	26.52
No. 3.....	Chlorid of potash.....	78.06	23.49
No. 4.....	Sulphate of ammonia.....	14.88	5.49
No. 5.....	Sulphate of potash.....	2.80	2.73

“When nitrate of soda is put into the soil, it is changed to nitrate of lime, which is highly soluble in water. The result is that if we put nitrate of soda where it will be washed out, it carries so much lime with it, so that nitric acid, despite its great value in special cases, is a lime robber. The same is shown concerning hydrochloric acid in the chlorid of potassium. . . . On the other hand, very much less of the sulphuric acid is washed out, and extremely little lime. This is a further claim in favor of the use of sulphate of ammonia. The former figures showed us that the ammonia is not washed out and we now see that the sulphuric acid in the ammonia sulphate does not act in causing a loss of lime as do the other two acids.”

Investigations in moor culture, H. IMMENDORFF (*Landw. Jahrb.*, 27 (1898), *Sup. 1*, pp. 503-521).—The work here reported consisted of investigations on the amount of plant food taken from moor and sandy soils by the removal of the grass and sod, and of analyses of *Molinia caerulea* and *Carex goodenoughii* and various crops for green manuring grown on upland moor and light sandy soils. The composition of the different plants is given in tables.

The grass and sod of moor lands are used for litter, and investigations were made to compare the amount of plant food removed from different kinds of soil by this practice. In this experiment 2,858 kg. of dried substance per hectare was removed from the sandy soil and 21,231 kg. from the moor soil. The substance taken from the sandy soil contained 179.657 kg. nitrogen, 72.693 kg. lime, 31 kg. magnesia, 53.394 kg. potash, and 22.416 kg. phosphoric acid, and the substance removed from the moor soil 201.482 kg. nitrogen, 89.170 kg. lime, 40.339 kg. magnesia, 33.917 kg. potash, and 19.108 phosphoric acid.

Action of lime and calcium carbonate on certain natural humus substances, G. ANDRÉ (*Compt. Rend. Acad. Sci. Paris*, 127 (1898), *No. 13*, pp. 416-418; *abs. in Ann. Agron.*, 24 (1898), *No. 12*, pp. 605-607; *Rev. Sci. [Paris]*, 4. ser., 10 (1898), *No. 15*, pp. 471, 472).—In the author's experiments samples of vegetable mold, moor soil, compost, and peat were heated for 15 hours in a water bath at 100° C. with lime, calcium carbonate, and water. The ammonia volatilized was collected. The extracts obtained were filtered, neutralized with hydrochloric acid, evaporated to dryness, and the nitrogen determined in the residues. The same substances were treated with lime in the cold for 82 days, with frequent shaking to promote the action of micro-organisms. Closed flasks were used to prevent loss of ammonia, and at the end of the period the alkaline solution obtained was distilled to determine the nitrogen in form of ammonia and easily transformed amids.

The amount of ammonia volatilized by lime at 100° C. was smaller than in previous experiments with potash (*E. S. R.*, 10, p. 830), but was considerable. With potash 17.01 per cent of the total nitrogen originally present in peat, 15.96 per cent of that in compost, 14.93 per cent of that in moor soil, and 13.61 per cent of that in vegetable mold, was driven off as ammonia, as against 10.86, 12.10, 9.23, and 10.45 per cent respectively with lime. The amounts of ammonia driven off in case of calcium carbonate and water were not important except in case of peat and compost. In these 2.89 and 5.33 per cent respectively were volatilized

in case of calcium carbonate and 2.38 and 3.75 per cent respectively in case of water.

The soluble nitrogen found in the lime solution was 19.50 per cent of the original nitrogen in case of vegetable mold, 21.26 per cent in case of moor soil, 40.91 per cent in case of compost, and 16.56 per cent in case of peat. These are all much lower percentages than were found in previous experiments with potash above referred to. The solutions obtained after treatment with calcium carbonate and water also contained considerable amounts of soluble nitrogen—1.82 and 1.23 per cent of the original nitrogen in case of peat, 6.4 and 5.61 per cent in case of vegetable mold, and 16.91 and 17.1 per cent in case of compost. The calcium carbonate extract of moor soil contained 6.71 per cent of the original nitrogen.

By the action of lime for 82 days at ordinary temperature 6.59 per cent of the original nitrogen in vegetable mold, 5.56 per cent of that in moor soil, 6.91 per cent of that in compost, and 5.73 per cent of that in peat was obtained in the form of ammonia and easily decomposed amids. These figures afford an indication of the changes brought about in soils by liming.

Contribution to the solution of the question whether the water content of the soil influences the nitrogen and ash content of the dry matter of plants, J. WILMS and C. VON SEELHORST (*Jour. Landw.*, 46 (1898), No. 4, pp. 113-126).—A continuation of work previously reported (*E. S. R.*, 10, p. 737). Oats were grown in pots of soil (about 17 kg., dry), which were either unfertilized or received different combinations of the 3 essential fertilizing constituents¹ and were watered at 3 different rates: (1) 41.6 per cent of the water capacity of the soil (small); (2) 45.2 per cent, increasing with the growth of the plants to 47.4 and 51.7 per cent (medium); and (3) 48.8 per cent, increasing to 53.2 and 63.7 per cent with the growth of the plants (large). The crop was cut when the grain was in the milk and nitrogen and ash determined.

It was found that the more productive the soil the greater the influence of its water content. The yield of straw and of grain was about equally increased by an increase in the water content of the soil. The influence of nitrogen in increasing the yield of straw was not affected by increasing the water content of the soil. However, with an excess of potash in the soil, increasing the water content increased the yield of straw and reduced the yield of grain. Increasing the water content reduced the nitrogen content of grain and straw to about the same extent. The nitrogen content of the crop varied with the amount applied in the fertilizer, and the effect of the nitrogenous fertilizers on the nitrogen content of the crop was greater the larger the amount of water present. The variations in nitrogen content due to the water

¹Potash in form of carbonate, phosphoric acid in monocalcium phosphate, and nitrogen in nitrate of soda.

supply were more marked in the case of the straw than in the case of the grain.

The ash content of the grain varied with the amount of water in the soil, increasing rapidly up to the point of medium water supply, but more slowly beyond that point. The fertilizing which gave the lowest yield of grain produced grain with the highest percentage of ash. The variations in the ash content of the straw due to the amount of water did not in all cases run parallel with those in the grain, but the variations due to fertilizing were of the same character in the straw and in the grain.

The potash content of the grain increased with the water content, rapidly at first, but more slowly with the larger amounts of water. The potash content of the grain increased with the amount of potash applied in fertilizer, as well as with the amount of water in the soil. The phosphoric acid content of both grain and straw was influenced to a much less extent than potash. However, the phosphoric acid content of the grain, as a rule, increased with the amount of water in the soil, the only exception being the cases in which combinations of phosphoric acid with nitrogen and phosphoric acid with potash were applied. The phosphoric acid content of the straw also increased, as a rule, with the water content of the soil, the only exception in this case being the crops to which potash, nitrogen, and double doses of phosphoric acid (2 gms. per pot) and potash and phosphoric acid with double doses of nitrogen (1 gm. per pot) were applied. The fertilizing influenced the potash content of the straw in the same manner as that of the grain, the potash content being especially large in the crops grown without fertilizers and with potash and nitrogen. The fertilizing exerted but little influence upon the phosphoric acid content of the grain, the increase being noted only when one of the other fertilizing constituents was lacking and the yield for that reason was small.

The forms of phosphoric acid in moor soils, G. NANNES (*Jour. Landw.*, 47 (1899), No. 1, pp. 45-48).—The ether-alcohol, hydrochloric acid (2 per cent), and ammonia (10 per cent) extracts of moor soils were studied. The ether-alcohol extract contained very little phosphoric acid, indicating the presence of only insignificant amounts of lecithin in the soil. More than half of the phosphoric acid present was insoluble in hydrochloric acid and ammonia (0.2 per cent out of a total of 0.38). Of the phosphoric acid extracted, 0.05 per cent was free and 0.13 per cent was combined with humus.

Attempts were also made to prepare and study the calcium, barium, cadmium, and lead compounds of humus, but without very definite results.

On the direct transformation of ammonia into nitric acid in liquid media, E. DEMOUSSY (*Compt. Rend. Acad. Sci. Paris*, 128 (1899), No. 9, pp. 566-569; *Ann. Agron.*, 25 (1899), No. 3, pp. 97-111).—The author calls attention to the fact that while it is recognized that both nitrous and nitric ferments are involved in the transformation of

ammonia into nitrates in the soil, it is rare that any nitrites are found to be present in the soil. In artificial liquid media, however, the action of the nitric ferment appears to be slower, as a rule, than that of the nitrous ferments, and nitrites thus accumulate more or less. The author succeeded, however, in preparing liquid media in which the ammonia was transformed directly into nitrates without the intermediary of nitrites.

Alkali studies, II, E. E. SLOSSON and B. C. BUFFUM (*Wyoming Sta. Bul. 39, pp. 35-56*).—In this bulletin the character of Wyoming alkali, studies of the effect of alkali on the germination of seed, field experiments on alkali soils with different plants, and the reclamation of alkali soils are discussed in a popular manner. In Wyoming alkali the sulphates predominate, black alkali being very rare in the State. The experiments made by the station indicate that the retarding effect of alkali on the germination of seeds is due to its hindering the seed from absorbing the water needed, and that this absorption "was influenced not by the kind of alkali or the strength of the solution, but purely by the osmotic pressure." In an experiment with wheat to test this point the following results were obtained:

Amount of water absorbed by wheat from salt and sugar solutions.

"It will be seen from the table that the wheat absorbed just about the same amount of water from each of these in the same length of time. . . .

"Beans absorb the same amount of water when put into a saturated solution of common salt as they do when put into pure water. The dissolved salt apparently passes into the bean as readily as the water and destroys its power of germination. Rye is intermediate between wheat and beans in this respect.

"To decide the question whether the absorption of water is physical or physiological, comparative tests were made between living seeds and seeds in which the power of germination had been destroyed by age, heat, or exposure to formaldehyde vapor. No difference between the living and dead seeds has been yet observed, so it appears that water is drawn into the seed purely by such physical forces as surface tension and osmotic pressure. It does not appear that the salts mentioned, except sodium carbonate, exert any poisonous influence on the wheat. It germinates readily when removed from the alkali solutions and put under favorable conditions."

In continuation of work reported in Bulletin 29 of the station (E. S. R., 8, p. 568), the following experiments were made:

"Seeds of wheat and rye were germinated in pure water and in solutions of sodium carbonate (black alkali), sodium chlorid (common salt), sulphate of sodium

(Glauber's salt), sulphate of magnesia (Epsom salt), and in sugar sirups of the same strengths as the salt solutions used. Each of the salts used and the sugar were applied to the seeds in strengths of 0.1 per cent, 0.4 per cent, 0.7 per cent, 1, 2, 3, 4, 5, 7, and 9 per cent solutions. The sugar was used to throw light upon a technical point."

From the results of these experiments the following table, showing the amount of salts which may be present without retarding the germination of wheat and rye seeds, has been prepared:

Amounts of different salts which may be present without retarding germination of wheat and rye.

	Magnesium sulphate.		Sodium sulphate.		Sodium chlorid.		Sodium carbonate.	
	In solution.	In soil.	In solution.	In soil.	In solution.	In soil.	In solution.	In soil.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Wheat.....	1.0	0.25	0.7	0.17	0.4	0.1	0.4	0.10
Rye.....	1.0	.25	.7	.17	.4	.1	.1	.02

"The salts are injurious in the order they are given in this table. The black alkali (sodium carbonate) is much more injurious than the other salts, because it has a corroding effect due to the fact that it is not a neutral salt, and free acid is present to produce a share of the damage. Of the salts composing the common white alkali magnesium sulphate seems to be the least injurious, while common salt (sodium chlorid) is most injurious. . . .

"It has been found that fewer seeds will live, and it takes longer for them to germinate as the strength of the solution increases, and there is a marked difference between the different salts. . . .

"Eighty-eight per cent of the seeds of wheat germinated in water. In 3 per cent solutions of the salts, amounting to nearly 0.75 per cent of salt in the soil, the following percentage of the wheat was germinated: Magnesium sulphate 86 per cent, sodium sulphate 70 per cent, sodium chlorid 35 per cent, and sodium carbonate 11 per cent. Ninety-six per cent of the rye germinated in water. In 3 per cent solutions of the salts the following percentage of rye germinated: Magnesium sulphate 92 per cent, sodium sulphate 56 per cent, sodium chlorid 38 per cent, and sodium carbonate 22 per cent. This would indicate that rye will stand stronger alkali than will wheat, which corresponds with results of previous tests. . . .

"In these experiments it has been a most notable fact that small amounts of alkali salts were beneficial or at least that they accelerated instead of retarded germination. No doubt small amounts present in the soil also assist in the life of the plant, either stimulating its growth or acting directly as plant food."

An extensive series of pot experiments with alkali were made. While these experiments were not conclusive as to the effect of alkali on plant growth, they gave interesting data regarding the evaporation of water from soils containing different amounts of soluble salts. "From the pots containing no alkali 17.7 cc. was evaporated each day, while the amount of water lost from those pots containing 9 per cent solutions (equivalent to 2.2 per cent alkali in soil with 24.5 per cent moisture) was approximately one half as much."

Plants which have shown alkali-resisting properties are briefly discussed. Those noted include saltbushes, English rape, Bokhara clover, and sugar beets.

The alkali of the Yellowstone Valley, M. WHITNEY and T. H. MEANS (*U. S. Dept. Agr., Division of Soils Bul. 11, pp. 39, pls. 17, figs. 3*).—This is an account of a preliminary study of the rise of alkali in

irrigated lands in the immediate vicinity of Billings, Montana. The Yellowstone Valley at this point is about 6 miles wide and bordered on either side by high bluffs—on the north the bluff is of sandstone and on the south of blue shale. The sandstone is a gray siliceous stone containing small but perceptible amounts of magnesium and sodium sulphates, which are either dissolved and carried away by the water which percolates through the rocks or accumulate in layers throughout the rocks. Where evaporation has gone on for some time these salts appear as white efflorescences on the surface.

“Underlying the sandstone and coming out from under the sandstone bluff there is a fine blue shale or slate which extends to an unknown depth. In an attempt to get artesian water at Billings a well was driven 900 ft. through this shale. No deeper record than this has ever been made at this place. The shale rises up from beneath the sandstone and forms the rough angular blue hills on the south side of the valley.

“The shale is penetrated with numerous fine cracks and joints running in all directions, and these are filled with fibrous gypsum. Many cavities also are found filled with gypsum and calcium carbonate. Everywhere throughout the shale large quantities of sodium and magnesium sulphates are found, which appear as white efflorescence where evaporation has taken place. . . .

“As the rocks weather, a portion of the soluble salts is removed in the springs and seepage waters, but the removal is not nearly so complete as is the case in the humid portions of the United States, because the small rainfall renders the escape of all of the excessive amounts of salts impossible.

“The two types of rock give rise to two distinct types of soil in the valley—one a sandy soil, derived from the disintegration of the sandstone rock, giving a soil of open texture, easily worked, in which there is less trouble from alkali on account of the more perfect drainage and less risk of the accumulation of seepage waters; the other type is a stiff clay or gumbo formed from the disintegration of the shales. These shale soils are extremely fertile when in good condition, but are quite difficult to work. They are easily puddled and are rendered almost impervious to water by the excess of the soluble salts which they usually contain, and it is upon these soils, with their poor underdrainage, that the greatest amount of trouble has arisen from the accumulation of seepage waters and salts in the overirrigation of the soils in the valley.

“Between these two extremes of sandy soil and gumbo, in areas where the layer of sandstone has not been completely removed, the soils are blended in all possible combinations, from the pure type of the sandy soil to that of the gumbo.

“The following table gives the mechanical analyses of a number of soils from Billings, which indicate the difference in the texture of the soils which has been noticed:

Mechanical analyses of soils near Billings, Montana.

"The first sample is a very pure type of sandstone soil taken from the top of the bluff about 2½ miles north of Billings and was derived from the decomposition of the soft layers of fine sandstone which cap the bluffs. These soils are very light and loose and have very free underdrainage. As a matter of fact, they leach readily, and, although they afford the best possible conditions for irrigation in that seepage waters are not likely to accumulate in them, it is probable that they would not last very long, as the soluble salts would easily and quickly be removed from them. Soils of this type are found in many parts of the valley, and there is little or no danger from seepage waters or from an accumulation of soluble salts at the surface, although they contain considerable quantities of such salts at depths below the surface.

"The other samples in the table are seen to grade up through the mixed sandy gumbo to the pure form of gumbo with from 27 to 35 per cent of clay. The mixed soils are the most abundant in the valley."

When this valley was first settled, there were no signs of alkali on the surface of the soil, but now, after 12 to 15 years of irrigation (usually excessive) many once fertile tracts on the lower levels have become flooded, "and alkali has accumulated on them to such an extent that they are mere bogs and swamps and alkali flats."

The alkali in this locality, as indicated above, consists mainly of magnesium and sodium sulphates, with no sodium carbonate and but a trace of sodium chlorid. Its composition, which is very constant throughout the region, is shown by the following average of 5 analyses by F. W. Traphagen:

Composition of the soluble salts at Billings, Montana.

	Per cent.
Sodium sulphate	57.41
Magnesium sulphate	27.59
Calcium sulphate.....	13.05
Potash sulphate.....	1.55
Silica.....	.33
	99.99

In order to determine the amount and distribution of the soluble salts in the different soils, both with and without irrigation—

"Three lines of borings were run—one of 5 miles in length and the others, for more detailed study, of about 1½ miles and one-fourth of a mile, respectively, in length. The longer section began above the ditch and went down toward the river; the others extended from an alkali flat and from a drainage ditch back into the higher levels. In each of these sections a number of borings were made and the salt content determined at every foot in depth down to 10 or, frequently, 15 ft. In addition to this, a section or square mile of land was studied in great detail and borings were made at frequent intervals to a depth of 10 or 15 ft. A number of special borings were also made to study the relation of the different types of soil to the amount and distribution of the salts."

The amount of soluble salts present was determined by means of the electrical apparatus devised by the Division of Soils (E. S. R., 9, p. 535; 10, p. 30). The results are given in tables and in a series of charts and maps. The latter show graphically the depth to standing water and the amount and distribution of soluble salts at different depths in the soil of the area examined. "As a result of the investigations at Billings it

was found that plants could just exist with 0.45 per cent of the soluble salts present, equivalent to about 15,000 lbs. per acre-foot, and this is taken as the limit of plant production" in the preparation of these charts and maps.

"The results of these investigations show that the ultimate source of the alkali is in the sandstone, and particularly in the shale or slate rocks from which the soils have been derived. Before irrigation was introduced the salts were present in rather large amounts, but well distributed throughout the soil, and not in such large quantities as to be injurious to crops. The injury is due entirely to overirrigation, to the translocation and local accumulation of salts by means of seepage waters, and to the imperfect drainage facilities in the compact gumbo soils and the inability of the soils to remove the excess of salts and of seepage waters. . . . The open sandy lands, having better underdrainage, are not likely to be injured by a rise of salts except from an excessive application of water or in the low places in the path of the drainage system, especially when these are underlaid, as they are liable to be, by the heavy gumbo subsoils. . . . The investigations show, further, the very disturbing fact that the injury need not be due to a local application of water, but to the injudicious application of large quantities of it in remote localities and on neighboring farms. . . .

"The investigations point clearly to . . . the necessity of great care in the application of water in the methods of irrigation. This care must be exercised not only for the land which is being irrigated, but for the adjoining lands on lower levels. . . .

"Where the damage has been done, or where the conditions are so imminent that ultimate ruin can be foreseen, the logical method of reclamation is in providing adequate systems of drainage to carry off the excess of water and the accumulated salts. . . . It may be too soon yet to urge an extensive system of underdrainage in the valley, but some small systems should certainly be introduced, if necessary by cooperation, for an object lesson when it is considered necessary and timely to protect against trouble or to reclaim lands already abandoned. . . .

"It must not be assumed, however, that a thorough system of underdrainage relieves one from exercising care and judgment in applying water to the land. There is less immediate danger of ruining the land, to be sure, but there are two things to be considered, namely, that an excessive use of water means just so much loss to irrigation and so much less land which can be brought under the ditch, and also that in the removal of these salts by the flow of the seepage waters out through the drainage system large quantities of really valuable plant food are likely to be removed from the soil. . . . By overirrigation and underdrainage we may remove in a few years the very conditions which contribute to the wealth of the country in the fertility of the soil.

"In taking up new land in the Yellowstone Valley the heavy gumbo soils should be underdrained at the time the first irrigation waters are applied to the land. . . . It is too late to wait until the damage has been done, for the accumulation of salts themselves acts on the heavy gumbo soils and makes them more impervious to water and harder subsequently to drain. Great care must be taken in the application of water. . . .

"The rise in the level of water in wells must be looked upon with uneasiness and guarded against with great care."

The advisability of cultivating such alkali-resisting crops as are known, or of finding or breeding others, is discussed, but it is considered unfortunate "for a locality like the Yellowstone Valley, which is originally free from alkali, to accept such conditions resulting from their injudicious methods of irrigation and try to find crops which will thrive upon lands which have been unnecessarily injured."

The causes of injury to plants by alkali are explained. "Field work in the alkali soils at Billings has shown that when the concentration of the salts in active solution in the soil moisture is as high as 1 per cent the limit of most cultivated plants is reached." The injury is due to the fact that when "the concentration of the soil solutions becomes greater than a 1 per cent solution the osmotic pressure of the solution outside of the cell is greater than the pressure of the solution inside the cell and the cell is unable to absorb water." (See also abstract of Wyoming Station Bulletin 39, p. 1025.)

"It has been found that the solid grains of soil have the remarkable power of absorbing or concentrating a portion of the salts on their surface and thus withdrawing them from active solution. This is of the greatest practical importance, as otherwise the soil moisture would quickly become saturated with salts and rendered totally unfit for agricultural plants. As a matter of fact, in consequence of this condensing power, in no case was the concentration of the soil moisture found to exceed 3 per cent, although the salts were quite soluble and were crystallized out on the surface of the ground."

Soil temperatures, L. G. CARPENTER ET AL. (*Colorado Sta. Bul.* 49, pp. 55-63, fig. 1).—The weekly averages of soil temperatures (recorded by two sets of thermometers) down to depths of 6 ft. are reported, and the effect of irrigation on the temperature of the soil is discussed.

"[One set of soil thermometers was so situated in a grass plat] that the irrigation of the lawn flooded to a depth of some inches the ground where the instruments were placed, and the irrigation was continued long enough to saturate the ground underneath.

"The temperature at a depth of 6 ft. had been nearly uniform at 62° for a number of weeks before the date of irrigation on August 12.

"With the application of water it is noticed that the temperature immediately rises, reaching a temperature of 71° almost immediately after. The temperature fell almost immediately after the irrigation, so that during the next 3 days it had fallen to 64.5°. On August 16 the irrigation was repeated, and this time the effect of this, added to the effect of the first, was to increase the temperature to 75.5°. The temperature dropped rapidly to 69°, and then dropped gradually, not again reaching 62° until October. The effect of irrigation on the plat of ground and its vicinity was felt for more than a month.

"The effect on the temperature at 2 ft. and at 3 ft. in depth was much the same. At the first irrigation the temperature at 2 ft. was increased over that at the lower depths. At the second irrigation the effect on the deep thermometers was almost as great as upon the 2-ft. thermometer.

"For the depths less than 2 ft. the diurnal fluctuation is marked. . . . The shallower thermometers also show the cooling effect from evaporation so much that their temperatures fell below the deeper ones."

The air and the methods of hygrometry, A. and H. WOLPERT (*Die Luft und die Methoden der Hygrometrie. Berlin: W. & S. Loewenthal, 1899, pp. XXII + 388, figs. 168*).

The maximum amount of chlorids in sea air, A. GAUTIER (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 12, pp. 715, 716*).—The author found in the air of the Atlantic Ocean 0.00462 gm. of chlorin, corresponding to 0.022 gm. of sodium chlorid per cubic meter of air.

The absence of iodine in the free state or in the form of iodated gas in the air of the region of Toulouse, F. GARRIGOU (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 14, pp. 884, 885*).

Researches on moorland waters: I, Acidity, W. ACKROYD (*Jour. Chem. Soc. [London]*, 75 (1899), No. 436, pp. 196-200, fig. 1).—An account of studies especially with reference to the fitness of such waters for drinking purposes.

A new chemical process for the purification of water to be used for irrigation, G. TRUFFAUT (*Jour. Soc. Nat. Hort. France. 3. ser.*, 21 (1899), Feb., pp. 184-190).—From the hardness, as determined with standard soap solution, the amount of monopotassium phosphate required to remove the larger part of the calcium and magnesium and convert the harmful salts into useful forms is calculated.

On methods of determining the fertilizer requirements of cultivated soils, O. KELLNER (*Mitt. Oekon. Gesell. Sachsen, 1897-98, II, pp. 16*).—A general discussion of this subject.

Directions for judging the agricultural value of soils, K. BIELER (*Monat. u. von Lengerke's Landw. Kalender, 1899, pt. 2, pp. 53-80, figs. 2*).—A popular discussion of the value of mechanical and chemical examination both of the surface and subsoil as means of determining the agricultural value of soils.

Soils and fertilizers, C. M. BLACKFORD (*Pop. Sci. Mo.*, 54 (1899), No. 3, pp. 392-401).

Analyses of the arable soils of Belgium, A. PETERMANN (*Rev. Gén. Agron.*, 8 (1899), No. 2, pp. 49-55; 3, pp. 113-120).

Soil analyses at Wollongbar, H. V. JACKSON (*Agr. Gaz. New South Wales, 10 (1899), No. 2, pp. 166-168, fig. 1*).—Analyses by F. B. Guthrie of samples from fertile and infertile spots of a deep, friable, well-drained red loam showed the infertile spots to be acid.

The nitrogenous compounds which accompany humus acids in soils and peat, F. SESTINI (*Landw. Vers. Stat.*, 51 (1899), No. 2-3, pp. 153-158).—See E. S. R., 10, p. 424.

Soil temperatures (*New York State Sta. Rpt. 1897, pp. 628-631*).—A tabulated summary of tri-daily observations during 1897 at depths of from 1 to 18 in.

FERTILIZERS.

Analyses and valuations of fertilizers, L. A. VOORHEES and J. P. STREET (*New Jersey Stas. Bul. 132, pp. 61*).—This bulletin gives trade values of fertilizing constituents in 1898 and the results of examinations of the standard commercial materials supplying them, as well as of home mixtures, factory-mixed fertilizers, and miscellaneous fertilizing materials. Analyses and valuations are given of 85 samples of standard raw materials, 305 brands of complete fertilizers, 28 samples of ground bone, 23 samples of home and special mixtures, and 38 samples of miscellaneous products. The materials examined include, in addition to the mixed fertilizers, nitrate of soda, sulphate of ammonia, dried blood, ground fish, tankage, ground bone, superphosphates, muriate of potash, sulphate of potash, kainit, double phosphate of potash and magnesia, saltpeter lime, lime from soft clam shells, shell marl, a lime fertilizer, wood ashes, crematory ashes, wool waste, bat guano from Mexico, cotton-seed meal, and pigeon manure.

The consumption of fertilizers in the State in 1897 was practically the same as in 1896. The 305 brands of fertilizers examined were the product of 81 manufactories, indicating a tendency to excessive multiplication of brands. The fertilizers examined furnished on an average the amount of plant food guaranteed, but in only 66 per cent of them was it distributed in the proportion stated. The average composition, estimated value, and selling price of all brands of complete fertilizers

examined during the year were as follows: Total nitrogen, 2.45; total phosphoric acid, 10.69; available phosphoric acid, 8.37; insoluble phosphoric acid, 2.32; potash, 5.38 per cent; station valuation, \$19.90; selling price, \$28.58; actual difference, \$8.68; percentage difference, 43.6 per cent. A comparison of these figures with similar data for previous years (E. S. R., 9, p. 935) shows that the composition of the average fertilizer has been remarkably uniform for the past 8 years.

The average cost per pound of nitrogen in the samples (12) of nitrate of soda examined was 12.33 cts.; of sulphate of ammonia (1 sample), 14.02 cts.; dried blood (9 samples), 11.52 cts.; ground fish (9 samples), 11.54 cts.; and ground bone (15 samples), fine, 11.19, and coarse, 8.29 cts. The average cost per pound of available phosphoric acid in plain superphosphate (15 analyses) was 3.34 cts. The average cost per pound of potash in muriate of potash (12 samples) was 3.82 cts.; in kainit (3 samples), 4.04 cts.

Virginia marls, W. B. ELLETT and A. T. ESKRIDGE (*Virginia Sta. Bul.* 78, pp. 65-70).—This bulletin reports analyses of 36 samples of marl from different parts of Virginia, accompanied by a brief review of the history of the use of marls in Virginia and a discussion of their value as a fertilizer. The analyses are grouped in three classes: (1) Marls containing upward of 20 per cent of lime (19 samples), (2) marls containing over 1 per cent of phosphoric acid (12 samples), and (3) marls containing over 1 per cent of phosphoric acid (5 samples). "The analyses make it clear that there are marls of high fertilizing value to be found in some sections of the State."

Investigations on the fertilizing value of carbon bisulphid, E. WOLLNY (*Vrtljschr. Bayer. Landw. Rath.*, 1898, No. 3, pp. 319-312).—This is an account of experiments in pots and in the field with a variety of crops, extending over several years and designed to test not only the direct, but the after-effect of carbon bisulphid. Two series of experiments were made; one in which the bisulphid was applied during the growing period of the plants and the other in which the bisulphid was applied some months before the planting of the crops. The results showed that in the former case the plants were either killed or their growth checked and the yield reduced, while in the latter case the yield was considerably increased. However, the yields the second or third year, if no fertilizer was applied, were smaller on those soils which had received the carbon bisulphid the previous year than on those which had not received an application of this substance. The causes of the peculiar action of the bisulphid were not explained by these experiments. The activity of the nitrifying organisms of the soils and of the organisms of the root tubercles of leguminous plants was checked, but the organisms were not killed even by the use of considerable quantities of bisulphid. The crops experimented with were beans, peas, carrots, beets, potatoes, rye, maize, mixed grasses, flax, clover, alfalfa, camelina, and rape. In the pot experiments 10 cc. of carbon bisulphid was used in each pot (containing 4.15 kg. of soil).

In the field experiments plats 4 square meters in area were used. In each plat 16 holes were made at regular intervals to depths of from 30 to 50 cm. and 25 cc. of carbon bisulphid applied in each hole.

Experiments to determine the fertilizer requirements of soils, G. LIEBSCHER ET AL. (*Jour. Landw.*, 46 (1898), No. 4, pp. 319-412).—This is an account of a continuation by Edler, Kretschmer, von Seelhorst, and J. Wilms of experiments planned by G. Liebscher (*E. S. R.*, 7, p. 664) to determine the fertilizer requirements of soils by means of field and pot tests, the latter accompanied by analyses of the soils and plants.

The results of field experiments with fertilizers in a number of different localities in 1895 were inconclusive, it being impossible to determine whether the differences observed were due to the fertilizers used or to variations in the other conditions. When, however, tests were made with the different soils in pots accompanied by a study of the composition of the soil and of the crop produced, more definite results were obtained. It was found in this case that, under like conditions of culture, heat, moisture, etc., plant analysis furnished a reliable means of judging of the fertilizer requirements of the soil. It is considered more reliable for this purpose than soil analysis, although the latter furnishes useful data. The conditions in pot experiments vary so widely from those which obtain in the field that, in the authors' opinion, there is a question whether the composition of the plants grown in the field would not differ materially from that of plants grown in pots. It was found in many cases that the potash content of the crop was increased by applications of phosphoric acid, although the opposite was rarely true. The results further show that a constituent which was in relative excess in the soil was also found in excess in the crop.

Barnyard manure, F. T. SHUTT (*Canada Cent. Expt. Farm Bul.* 31, pp. 29, pl. 1).—This is a popular article on the nature, functions, composition, fermentations, preservation, and application of barnyard manure based to a large extent on investigations made by the author and his associates.

Report of analyses of commercial fertilizers for the fall of 1898, L. L. VAN SLYKE (*New York State Sta. Bul.* 148, pp. 199-225).—The results of analyses of 162 different brands of fertilizers are reported and the composition and quality of the different fertilizers offered for sale in the State during the year 1898 are discussed. Of the 162 brands examined, 111 were complete fertilizers. In these the nitrogen varied from 0.46 to 4.69 per cent, averaging 1.67 per cent; the available phosphoric acid varied from 4.77 to 13.45 per cent, averaging 9.27 per cent; the potash varied from 0.36 to 10.43 per cent, averaging 4.36 per cent. The average amounts of nitrogen, available phosphoric acid, and potash exceeded the guaranteed average by 0.16, 0.96, and 0.26 per cent, respectively.

Analyses of fertilizers, C. A. GOESSMANN (*Massachusetts Hatch. Sta. Bul.* 57, pp. 24).—The bulletin contains analyses of 57 samples of fertilizing materials sent to the station for examination and 127 brands of commercial fertilizers collected during 1898. The fertilizing materials analyzed include wood ashes, limekiln ashes, peach-twig ashes, potatoes, clover hay, tobacco stems, hop refuse, dried blood, peat, sulphate of ammonia, sulphate of potash and magnesia, tankage, bone meal, barnyard manure, sewage, and complete fertilizers. A schedule of trade values for 1898 is given.

The Peruvian guano deposits from 1878 to 1898, J. H. M. FALLON (*Jour. Soc. Chem. Ind.*, 18 (1899), No. 3, pp. 213-224, figs. 4).—A brief history of these deposits.

Analyses of bat guano, F. WATTS (*Jour. Jamaica Agr. Soc.*, 3 (1899), No. 3, p. 175).—Analyses of samples of medium and rich quality, representative of deposits on the island of Jamaica.

The potash industry, H. PASSMANN (*Die Kaliindustrie in ihrer Bedeutung und Entwicklung*, 2 ed. Stassfurt, 1899, pp. 111+120).

Phosphatic nodules of Trichinopoly and the use of mineral phosphates in agriculture, D. HOOPER (*Agr. Ledger*, 1898, No. 20 (*Agr. ser.*, No. 28), pp. 19).—These nodules, which are found scattered over the surface or distributed through the soil in more or less abundance over a considerable area in this district, showed on analysis 53 to 69 per cent of tricalcium phosphate, 4 to 8 per cent of oxid of iron and alumina, and 12 to 23 per cent of calcium carbonate.

The value of the lime in phosphatic fertilizers, MAZILLÈRES (*L'Engrais*, 14 (1899.) No. 8, pp. 179-181).—A discussion, based largely upon the work of Ullmann, of the fertilizing value of the free lime of Thomas slag and the gypsum of superphosphates.

Remarks on the determination of the fertilizer requirements of soils, C. VON SEELHORST (*Jour. Landw.*, 47 (1899), No. 1, pp. 91-94).—An explanation of some of the details of the experiments reported in the article noted above (p. 1033).

Fertilizers for natural meadows (*L'Engrais*, 13 (1898), No. 41, pp. 977, 978).—A summary of the results of investigations on this subject, with conclusions.

FIELD CROPS.

Results obtained in 1898 from trial plats of grain, fodder corn, and roots, W. SAUNDERS (*Canada Cent. Expt. Farm Bul.* 32, pp. 47, figs. 2).—These tests were in continuation of cooperative work previously reported (*E. S. R.*, 9, p. 826). The general plan of the experiments remained unchanged. The results are given in tabular form.

Taking the average results obtained on all the experimental farms the varieties of the different crops producing the largest yield in 1898, mentioned in their order, were as follows:

Oats.—Bavarian, Banner, White Giant, Oderbruch, Columbus, American Triumph, American Beauty, California Prolific Black, Abundance, White Schonen, Mennonite, and Golden Beauty. *Two-rowed barley*.—Beaver, Dunham, Danish Chevalier, Newton, French Chevalier, and Prize Prolific. *Six-rowed barley*.—Pioneer, Stella, Odessa, Mensury, Oderbruch, and Trooper. *Spring wheat*.—Wellman Fife, Monarch, White Connell, Goose, White Fife, Red Fife, Preston, Progress, Percy, Rio Grande, Stanley, and Emporium. *Peas*.—Perth, Pride, Elephant Blue, King, Harrison Glory, Trilby, Vineet, Early Britain, Pieton, New Potter, German White, and Bruce. *Corn*.—Red Cob Ensilage, Giant Prolific Ensilage, Thoroughbred White Flint, Early Mastodon, Champion White Pearl, and Cloud Early Yellow. *Turnips*.—Purple-top Swede, Jumbo, Giant King, Sutton Champion, Hall Westbury, and Perfection Swede. *Mangel-wurzels*.—Yellow Intermediate, Gate Post, Giant Yellow Globe, Canada Giant, Giant Yellow Intermediate, and Norbiton Giant. *Carrots*.—Mammoth White Intermediate, Improved Short White, Half Long White, White Belgian, Green Top White Orthe, and Giant White Vosges. *Sugar beets*.—Danish Red Top, Danish Improved, Red Top Sugar, and Improved Imperial. *Potatoes*.—American Giant, Seedling No. 7, Date Puritan, New Variety No. 1, American Wonder, Irish Daisy, Dreer Standard, Clay Rose, Green Mountain, State of Maine, Polaris, and Rural Blush.

The average yields per acre in 1898 of the varieties here mentioned were approximately as follows: 69 bu. of oats, 42 bu. of two-rowed bar-

ley, 47 bu. of six-rowed barley, 30 bu. of spring wheat, 40 bu. of peas, 22 tons of silage corn, 33 tons of turnips, 33 tons of mangel-wurzels, 25 tons of carrots, 24 tons of sugar beets, and 453 bu. of potatoes.

The varieties of different crops which have given the best average yields at the several experimental farms during the past 4 years, in the order of their productiveness, are as follows:

Oats.—Banner, American Beauty, Columbus, Golden Beauty, Bavarian, Holstein Prolific, White Schonen, Early Golden Prolific, Wallis, Abundance, Golden Giant, and White Russian. *Two-rowed barley*.—French Chevalier, Danish Chevalier, Beaver, Canadian Thorpe, Newton, and Prize Prolific. *Six-rowed barley*.—Mensury, Odessa, Trooper, Common, Royal, and Oderbruch. *Spring wheat*.—Preston, Wellman Fife, Monarch, Percy, Red Fife, White Fife, White Connell, Rio Grande, Goose, Red Fern, Old Red River, and Advance. *Potatoes*.—Irish Daisy, Seedling 230, Late Puritan, American Wonder, Reading Giant, New Variety No. 1, Lee Favorite, Empire State, State of Maine, McKenzie, Clark No. 1. and Queen of the Valley.

The approximate average yields of these varieties of oats, two-rowed barley, six-rowed barley, spring wheat, and potatoes was 67.34.46.29, and 343 bu. per acre respectively.

The varieties of peas, mangel-wurzels, and carrots giving the best average yields for 3 years at all the experimental farms were as follows:

Peas.—Crown, Carleton, Pride, New Potter, Prince Albert, Arthur, Centennial, Paragon, Creeper, Trilby, Duke, and Kent. *Mangel-wurzels*.—Gate Post, Giant Yellow Intermediate, Yellow Intermediate, Giant Yellow Globe, Mammoth Long Red, and Canada Giant. *Carrots*.—Improved Short White, Half Long White, Giant White Vosges, Mammoth White Intermediate, Iverson, Champion, and White Belgian.

The approximate average yields of these varieties of peas, mangel-wurzels, and carrots were 34 bu., 30 tons, and 18 tons per acre respectively.

The effect of different methods of culture on the yield of mangel-wurzels. E. WOLLNY (*Bt. Zuckerrübenbau*, 5 (1898), No. 15, pp. 225-232; 16, pp. 241-248).—Ridge and level culture were compared, and a method, which consisted in making broad and flat-topped ridges along the middle of which the seed was planted and then level cultivation given, was tried. The data obtained show that the temperature of the ridged soil was higher and subject to greater variations than the soil which was given level cultivation; that the ridged surface had the smaller water content; and that the effect of drought is most marked on soils of a comparatively small water-holding capacity. It was found that ridges running north and south had a higher and less variable temperature than ridges extending east and west. The author concludes that ridge culture and growing plants on broad and flat ridges is advisable only on soils with large water-holding capacity and in moist climates. The general conclusion is that growing beets on broad and flat-topped ridges with level cultivation in a mild and moist climate and on soils of medium to large water-holding capacity is preferable to the ordinary ridge culture.

A report of the cultural experiments at the agricultural college at Carlsburg (*Bul. Agr. [Brussels], 14 (1898), No. 6, pp. 612-619, pl. 1*).—The results of fertilizer and cultural experiments with oats and potatoes carried on for 13 years are tabulated, and the results obtained during the season of 1898 are discussed in detail. The fertilizers applied were barnyard manure, a complete commercial fertilizer, a fertilizer which furnishes nitrogen only, and fertilizer mixtures in which either nitrogen, phosphoric acid, potash, or lime was lacking. In general, barnyard manure gave the best results.

Harrowing meadows proved effective in the destruction of weeds. Spraying a weedy field of oats with a solution of a mixture of copper sulphate and ferrous sulphate ($7\frac{1}{2}$ kg. per hectoliter of water) resulted in the destruction of the weeds without a bad effect on the oats or the clover which grew under it.

Distance experiments with sugar beets and fertilizer tests with potatoes, C. VON SEELHORST (*Fühling's Landw. Ztg., 47 (1898), No. 8, pp. 300-302*).—Better results were obtained when beets were planted 20 cm. apart in rows 20 cm. apart than when either of the distances was 30 or 40 cm. The fertilizer experiment with potatoes showed that kainit, carnallit, and muriate of potash, when applied late, decrease the starch content of the tubers, while sulphate of potash and carbonate of potash and magnesium increased the starch content. Muriate of potash, sulphate of potash, and carbonate of potash and magnesium were the most effective in increasing the total yield.

The composition of sugar beets rich in sugar (*Chem. Ztg., 22 (1898), No. 98, p. 1035*).—In 1898 1,200 samples of sugar beets analyzed in the State Laboratory at Löwen, Belgium, showed an average sugar content of 16.4 per cent. From a comparison of the composition of rich sugar beets it is concluded that the percentages of nitrogenous and mineral substances and cellulose decreases as the sugar content increases; further, that the sugar content of the beet increases as the percentage of lime in the beet increases and the percentages of potash and phosphoric acid decrease and that the content of magnesia remains relatively the same.

The influence of different rates of fertilization on the yields of cultivated plants, E. WOLLNY (*Bl. Zuckerrübenbau, 5 (1898), No. 4, pp. 369-373*).—From the results of growing sugar beets, mangel-wurzels and potatoes fertilized with different amounts of a mixture consisting of equal parts of superphosphate, chlorid of potash, and nitrate of soda, the author concludes that the yield increased with the increase of plant food up to a certain point, when the rate of increase in the yield began to diminish and finally reached a point beyond which the increase of plant food became unprofitable.

Report of field experiments, 1897-98, A. DAMSEAUX (*Bul. Agr. [Brussels], 14 (1898), No. 6, pp. 591-605*).—The results of fertilizer experiments with cereals and root and forage crops are reported. Among 13 varieties of wheat Carter D, Barbu jaune à épi carré, Standup, and Rivett Bearded, in the order given, were the most pro-

ductive. Two varieties of rye, Lochow and Bannet, and 1 variety of oats, La Précoce d'été Chrestensen, are recommended. A dressing of 400 kg. per hectare of superphosphate produced a larger increase in the yield of oats than a dressing of 200 kg. per hectare of nitrate of soda, and when these applications were applied together the results were not as satisfactory as when they were applied separately. The use of Alinit seemed to have no effect on the yield of oats.

Eight varieties of sugar beets were grown, all of which showed a high sugar content and coefficient of purity and a good yield. The following varieties are mentioned as producing beets of good form: Rimpau à Schlanstedt, Keillholz améliorée, Selection Dumont-Brabant, and Baumeier Kleinwanzleben. Nitrate of soda and sulphate of ammonia were applied before the sugar beets were planted. The nitrate of soda increased the yield at the expense of sugar content and purity, while the sulphate of ammonia had no detrimental effect on the sugar content and purity, but produced a smaller increase in yield. Muriate of potash was found more effective than kainit.

The results of testing gypsum as a fertilizer for clover showed that the application should not be made as a top-dressing.

Tests were made of fertilizing and cultivating the sod of two-year-old meadows. Peruvian guano was applied at the rate of 350 kg. per hectare on February 21 and cultivation with a harrow was given to the depth of 6 cm. The fertilizer applied alone gave the best results, followed in their order by the use of the fertilizer together with cultivation, and cultivation alone.

Test of fertilizers on wheat, D. O. NOURSE (*Virginia Sta. Bul.* 77, pp. 53-61).—This is in continuation of work formerly reported, and the plan of the experiment has been described in a previous abstract (*E. S. R.*, 9, p. 747). The results for the present year and the average results for 3 years are given in tables. The financial results of the different applications are discussed. The average results for the 3 years show that when applied alone potash was practically without effect, nitrogen increased the yield, but not enough to pay for the application, and phosphoric acid more than doubled the yield of grain and straw. The following table gives the results obtained when the fertilizers were applied together, each in amounts sufficient to supply either all the phosphoric acid or one-half of the potash or nitrogen removed in a crop of wheat of 25 bu. per acre.

Results of fertilizer tests with wheat.

Plant food.	Grain per acre.				Straw per acre.

A contribution to the question of how kainit affects the potato when applied to the preceding crop, O. LEMMERMANN (*Landw. Vers. Stat.*, 51 (1898), No. 2-3, pp. 159-181).—A number of cooperative experiments were made with different amounts of kainit applied to the cereal crop which preceded a crop of potatoes. In every case 9 plats each 5 ares in size were used. In addition to uniform green manuring and an application of 1,000 kg. of lime per hectare, 3 received 1,000 kg. kainit per hectare, 3 received 2,000 kg., and 3 received no kainit. The fertilizers were applied in the fall of 1894. A cereal crop was grown the following season, and in 1896 a crop of potatoes. The results from the kainit applications on the cereal crop indicate that on soils containing 0.2351 per cent of potash a potash fertilizer for wheat and rye is recommendable, and that on soils containing 0.2424 per cent of potash an addition of potash is unnecessary for oats.

In general the application of kainit in these experiments acted beneficially, but the results from different amounts on the various soils were not parallel. In all cases except one, plats receiving kainit produced better yields than plats to which no kainit had been applied. The yield from the larger applications was greater in a number of cases than the yield from the smaller applications, but the increase was not in proportion to the amount applied. In a few instances the application of 2,000 kg. per hectare proved too heavy, and the yields were smaller than those obtained on plats which had received one-half that amount or no kainit. The action of kainit in these tests did not show any marked regularity, and the author considers further experiments necessary before definite conclusions can be drawn.

Researches on the quantities of fertilizing materials necessary in the intensive culture of the potato, A. GIRARD (*Ann. Sci. Agron.*, 1897, II, No. 2, pp. 261-280).—Observations were made of the amount of plant food removed from the soil by the different parts of the potato plant. Eight different varieties were studied. It is concluded that the maximum yields of tubers of these varieties removed on an average 110.80 kg. of nitrogen, 25.31 kg. of phosphoric acid, and 183.35 kg. of potash per hectare.

On the consumption of water in rice fields, I. INAGAKI (*Imp. Univ. Col. Agr. [Tokyo] Bul.*, Vol. 3, No. 5, pp. 407-414, pl. 1).—This article gives a record of measurements at intervals of two or three days of transpiration from rice plants growing in pots. The experiments covered the period from January 18 to October 20. The pots were covered with an apparatus which maintained the water in the pot at a constant level, measuring the water so used and at the same time recording the evaporation from the surface of the pots as well as the excess of water which the plants received due to wind, rain, or diminution of atmospheric pressure. From the data obtained in these experiments it is estimated that the rice crop transpires 1.539 liters of water per hectare per second. In experiments in the field it was found

that the amount of water so utilized by the rice plant was 1.068 liters of water per hectare per second. It thus appears that the water requirements of rice are much smaller in Japan than in Italy, where, according to Patriarca,¹ the average amount of water required by rice is 2.637 liters per hectare per second. This difference is believed to be due to the greater humidity of the air in Japan (76 to 94 per cent. as compared with 52 to 69 per cent in Italy).

Report of the agricultural exposition of Kiev and the agricultural industries of Russia, H. SAGNIER (*Bul. [Min. Agr. France], 17 (1898), No. 2, pp. 488-513*).—This report discusses the agricultural exposition held at Kiev in 1897 and the history and present condition of agricultural education in Russia, and gives descriptions of the Agronomic Institute at Moscow, the Imperial Agricultural Museum, and the Botanic Gardens at St. Petersburg. An outline is given of the systems of agricultural experiment stations and meteorological stations and the general work of the Ministry of Agriculture is pointed out.

November crop report, C. C. JAMES (*Ontario Bureau Ind. Bul., 68, pp. 31*).—This bulletin gives the estimates of the yields of crops, statistics of live stock, and the total rainfall and average temperature for the Province of Ontario for 1898.

Some statistics of the world's production and consumption of cereals, L. GRANDEAU (*Ann. Sci. Agron., 1898, II, No. 2, pp. 177-228*).—Figures are given on the production of cereals in general, on the production of wheat for all countries, and on the cost of producing wheat in France.

The culture of beets for forage, E. MER (*Prog. Agr. et Vit. (ed. Est), 20 (1899), No. 13, pp. 399-401*).—This article reviews the methods of growing beets for forage in different parts of France and gives directions for their culture.

Broom corn (*Wallace's Farmer, 24 (1899), No. 14, p. 313*).—A popular note on the culture of broom corn in central Kansas.

Cost of cane culture, R. E. ROSE (*Florida Agr., 26 (1899), No. 15, p. 27*).—A brief article on the cost of growing sugar cane in Florida and Louisiana.

The cultivation of pindars or ground nuts in Jamaica, F. WATTS (*Jour. Jamaica Agr. Soc., 1898, No. 10, pp. 409-414; abs. in Jour. Soc. Chem. Ind., 17 (1898), No. 12, p. 1200*).

General observations on oats, BALLAND (*Compt. Rend. Acad. Sci. Paris, 125 (1897), No. 16, pp. 579-581*).

Raising peanuts by irrigation (*Fla. Agr., 26 (1899), No. 15, pp. 26, 27*).—A brief article on the subject.

Some good varieties of potatoes (*Amer. Gard., 20 (1899), No. 226, p. 301*).—Notes on 16 of the newer varieties of potatoes tested at the Ohio Station the last two seasons.

The potato in France in 1781, G. HENSLOW (*Gard. Chron., 3, ser., 25 (1899), No. 639, p. 177*).—A review of a work on the potato published in France in 1781, containing many points of historical interest.

The influence of form, size, and starch content of seed potatoes on the yield, M. FISCHER (*Fühling's Landw. Ztg., 48 (1899), No. 5, pp. 188-193; 6, pp. 201-208*).—Experiments were conducted to determine the influence of these factors on the yield of potatoes, and the results are here tabulated and discussed.

Relations between the color of the grain, its composition, and the form of the heads and stems of rye, N. WESTERMEIER (*Fühling's Landw. Ztg., 47 (1898), No. 22, pp. 847-852*).—This article is a discussion of the results of breeding rye by different breeders. The author states that so long as it has not been proved that yellow-grained rye is the more productive, green-grained rye should receive the preference

¹ Compare Markus, Landw. Meliorationswesen, 1881, p. 59.

on account of its higher nitrogen content. A discussion of this subject has been previously noted (E. S. R., 10, p. 319).

The British millers' requirements in wheat (*Agr. Gaz. New South Wales*, 9 (1898), No. 1, pp. 750-761).—The article considers the wheat berry, the endosperm, and the germ, besides discussing the milling requirements in a general way.

Experiments in the improvement of fodder roots, C. V. GAROLA (*Ann. Sci. Agron.*, 1898, II, No. 3, pp. 423-459).—Results are given of cultural experiments and investigations on the chemical composition and digestibility of fodder roots.

The chemical composition of maize and its products, H. W. WILEY (*Ann. Agron.*, 25 (1899), No. 1, pp. 33-41).—This is a translation by E. Gain of U. S. Dept. Agr., Division of Chemistry Bul. 50 (E. S. R., 10, p. 624).

Legumes in their relation to crop rotations, SALFELD (*Deut. Landw. Prusse*, 26 (1899), No. 24, pp. 259, 260).—A discussion on the value of various legumes in the rotation, with a statement of results obtained in practice.

HORTICULTURE.

The Stringfellow root-pruning theory, H. N. STARNES (*Georgia Sta. Bul.* 10, pp. 147-179, pl. 1, figs. 25).—The Stringfellow method of close root pruning is described and illustrated and the advantages claimed for it enumerated. They are, in short, a saving of time, labor, and consequent expense in handling, and a nearly perpendicular downward growth of the roots of the transplanted tree. In the first experiment one-year-old trees of Elberta peaches averaging 5 ft. in height were planted February 1, 1896, on red loam with a stiff red clay subsoil. There were 12 rows, each containing 21 trees, the rows being 18 ft. apart. The roots of the trees in the different rows were either unpruned, pruned only when broken, or pruned to 1, 2, or 4 in. clubs, or 1 or 4 in. taps, the tops in all cases being pruned to 18 in.; or the roots were pruned only where broken and the tops left unpruned or pruned to 12 or 24 in. At the same time in another location there were planted several small plats of apples and cherries, either unpruned or root-pruned to 1 in. clubs with tops pruned to 18 in. All trees with whole roots were planted in the usual manner in standard holes and the rootless ones in a crack made by inserting a spade perpendicularly in the ground and withdrawing it.

The season which followed was exceptionally dry, yet every tree lived and appeared to flourish. At first the trees having whole or nearly whole root systems appeared to make the most rapid growth, but by fall there was little difference observable except in the rows that had not been top-pruned. The trees in these rows were less symmetrical than others, and showed a distinct warp or inclination toward the north. Little difference, if any, was observable between the rows whose tops had been pruned to 12, 18, and 23 in., respectively, all branching equally low.

The following winter one tree from each row was dug up and the dirt carefully washed away, thus exposing the entire root system. All were found so uniform in size, habit of growth, and general characteristics

that a second test of one-year-old roots was made. In this fewer trees were used, and McIntosh was substituted for Elberta.

One tree from each row was dug up, the roots freed from dirt, and photographed.

The assertion that the new root system will penetrate almost perpendicularly downward is not supported by these experiments. It is possible, however, that in more sandy ground the roots would assume a more nearly perpendicular direction. In the second experiment the best growth, both aerial and underground, was found in the rows which had been pruned to 4-in. taps and 1-in. tap planted in dibble holes. Observations upon the roots of two years' growth in the first experiment are given in the following table:

Roots after two years' growth.

Treatment.	Average diameter of root system.		Weight.	Depth of root system.	Diameter of stem.
	<i>Ft.</i>	<i>In.</i>			
1-inch club.....	8	0	5.93	19.0	2 $\frac{1}{2}$
2-inch club.....	7	0	7.47	20.0	2 $\frac{1}{2}$
4-inch tap.....	7	6	8.68	18.0	2 $\frac{1}{2}$
4-inch club.....	8	0	10.66	15.5	2 $\frac{3}{8}$
Pruned only where broken.....	10	1	14.30	17.5	3 $\frac{1}{8}$
Roots unpruned.....	9	1	11.04	15.0	3
1-inch tap planted in dibble hole.....	10	10	8.04	20.5	2 $\frac{1}{2}$
1-inch tap planted in normal hole.....	11	3	8.95	19.3	2 $\frac{3}{4}$

In all cases the taps were pruned to 18 in. The best and finest root systems were found in the trees pruned to 1-in. tap and planted in dibble or normal hole. The weight and diameter of stem was less than in others, but the roots penetrated much deeper. The whole root system had more fibrous laterals.

The apples and cherries were examined at the end of the second season, and the difference between the unpruned and closely pruned roots was found much more pronounced. The latter made fewer, larger, and more robust roots, penetrating to a depth of 17 $\frac{1}{2}$ in. The former made a mass of small laterals, penetrating to only 9 $\frac{1}{2}$ in. The author is fairly satisfied that peach, apple, and cherry trees pruned by the Stringfellow method will live and flourish in his section of Georgia, even in stiff soil and under adverse meteorological conditions.

Orchard notes, F. S. EARLE (*Alabama College Sta. Bul. 98, pp. 263-277*).—Notes are given on the possibilities of successful apple culture in Alabama. An orchard of about 45 varieties was planted on the station grounds in 1885. Of these 24 varieties are enumerated which have proved healthy and fairly vigorous in that locality. The following provisional list covering a range of seasons is suggested: Early Harvest, Red Astrachan, Carter Blue, Limbertwig, York Imperial, Shockley, Red June, Horse, Ben Davis, Winesap, and Yates. "The two most serious enemies to profitable apple growing so far encountered are the various summer rots that attack the green fruit on the tree and

the green louse or aphid," the latter being very abundant, especially on young trees. It has not been found possible to rid the trees of them by kerosene emulsion. The apple scab is seldom seen. Notes are given on 20 varieties of Hungarian apples received from the Division of Pomology of this Department. "There were 3 trees of each kind, one of which had been grafted on a whole root, one on the upper half of a root, and one on the lower half of a root." Grafts on the lower half of the root made a slightly better growth than the others, and those on whole roots slightly poorer. In a test of northern as compared with southern grown apple nursery stock, Missouri-grown trees averaged 10 days earlier in starting than Georgia and Alabama stock, but before the end of the season there was no difference between them.

In a trial of Japanese as compared with French pear stocks for the South, Bartlett pears on the former were from the outset the more vigorous, and at the end of three seasons' growth averaged twice the size of those on French roots. In a trial of the Stringfellow root-pruning method with 8 varieties of peaches and 2 of pears, neither increase nor decrease of vigor could be detected in the root-pruned trees.

Observations made on the blooming seasons of 46 varieties of plums are given. The varieties are grouped as to time of blooming in the neighborhood of Auburn, each group comprising those blooming near enough together in ordinary seasons to effect cross pollination. A test of spraying with whitewash to retard blooming (E. S. R., 9, p. 835) showed little if any effect on time of budding.

Japanese persimmons, it is stated, grow readily in all parts of the State and bear well. Varietal notes are given on 9 sorts. Okame, Yeddo Ichi, Costata, and Yemon are recommended as the best market kinds.

Apples in Pennsylvania. G. C. BUTZ (*Pennsylvania Sta. Bul.* 43, pp. 17).—This is a popular bulletin, giving notes on soil, tilling the soil in young orchards, cultivation in bearing orchards, fertilizers, the trees, pruning at time of planting, distance to plant, pruning bearing trees, top grafting or double working, choice of varieties, preservation of apples, spraying, insect enemies, and fungus diseases. The greatest activity in Pennsylvania in the planting of apple orchards on a large scale is displayed at present in the southern and southwestern parts of the State. The author considers the York Imperial a variety of special promise in Pennsylvania.

Among the insect enemies of the apple are mentioned the codling moth (*Carpocapsa pomonella*), borers, oyster-shell bark-louse (*Mytilaspis pomorum*), cankerworm (*Anisopteryx pometaria*), aphid (*Aphis mali*), and tent caterpillar (*Clisiocampa americana*), and remedies are given.

Brief notes are given on the apple scab (*Fusicladium dendriticum*), rust (*Ræstelia pirata* and *Gymnosporangium macropus*), and leaf spot (*Phyllosticta limitata*), and remedies are suggested.

Tests of strawberries, raspberries, blackberries, and grapes. J. TROOP (*Indiana Sta. Bul.* 73, pp. 78-92, figs. 3).—Notes are given upon

numerous varieties of strawberries, raspberries, and blackberries, mostly new, tested at the station the past season. No recommended list of strawberries is given. Among raspberries, Miller, Cuthbert, Columbian, Golden Queen, Marlboro, Eureka, Kansas, and Nemaha are recommended; among blackberries, Agawan, Ancient Briton, Early King or Early Harvest (with protection), Eldorado, Erie, Snyder, Taylor, and Western Triumph. The author especially recommends thorough subsoiling before the setting of raspberries on land with a hard compact subsoil.

Cultural notes are given on the native grapes, and Brilliant, Campbell, Early Ohio, Nectar, Red Bird, and Ulster are recommended among the newer varieties as worthy of consideration.

Strawberry culture—notes on varieties, L. R. TAFT and H. P. GLADDEN (*Michigan Sta. Bul.* 163, pp. 43-76, figs. 6).—A general presentation of the subject, discussing the soil and its preparation, plants and planting, fall planting, varieties, perfect and imperfect flowered varieties, cultivation and care, mulching, preventing injury from frost, irrigation, cleaning out the old beds, insects and diseases, the strawberry weevil, and the strawberry-leaf blight. Notes upon a large number of varieties are appended.

"The most promising of the new sorts are Fountain, Hoosier, Knight, Morgan Favorite, Ridgeway, Seaford, Unnamed, and Mayflower for early and medium, and Michigan for late.

"Of the varieties that have been tested for two seasons the following have the most promise: Fremont, Giant, Glen Mary, Ideal, Purdue, Plow City, Ruby, and Wm. Belt.

"Notwithstanding the advent of the many newer sorts, it is doubtful if there are more profitable varieties for the market grower than Babach, Haverland, and Warfield, with Beder Wood, Sharpless, or Clyde as fertilizers for these pistillates.

"For the grower of fancy fruit under intensive culture it is possible that the large fruiting sorts—Brandywine, Glen Mary, Marshall, and Wm. Belt—may be more profitable than the varieties named above that are usually more productive but bear smaller berries.

"Bird, Greenville, Leroy, Snowball, and Weston, among sorts not so widely known as the above, have given good results as market berries.

"Aroma and Eureka bear large fruits, are late, and have a long season. They are well worthy of trial as late varieties."

A native white bedding plant, J. C. ARTHUR (*Indiana Sta. Bul.* 71, pp. 94-100, pls. 6, fig. 1).—The essential motive of this bulletin is to call the attention of flower lovers to the ornamental possibilities of some species of our native flora. Notes are given on *Cerastium arvense oblongifolium*, to which the author gives the popular name starry grasswort, as a bedding plant. This plant has been under cultivation at the station for several years. It covers the ground with a close mat of foliage and is evergreen. It has merits also as a cut flower. The starry grasswort is believed to possess the necessary capacity for variation that is essential when rapid cultural improvement is demanded. Botanical and cultural notes are given.

Horticulture in Japan, J. K. M. L. FARQUHAR (*Florists' Exchange*, 11 (1899), No. 12, p. 343).

Evolution in the garden, F. W. BURBRIDGE (*Gard. Chron.*, 3. ser., 25 (1899), No. 639, pp. 177, 178).—A criticism of the present confused nomenclature of garden plants, especially crossed plants, with suggestions for its simplification.

Orchard cultivation, J. T. STINSON (*Arkansas Sta. Bul.* 55, pp. 87-100, figs. 7).—A popular presentation of the subject, treating of location, soil, time for setting trees, distances between trees, how to transplant, how to prune, tillage, cover crops, and fertilizers. Apple skin blotch (*Leptothyrium pomi*) is mentioned as of rare occurrence in orchards on the highlands in the northwestern part of the State, but of extensive occurrence in less elevated locations. Experiments with the close root pruning method resulted somewhat unfavorably, but not decisively.

The science of fruit tree fruitfulness simplified (*Agr. Jour. Cape Good Hope*, 11 (1899), No. 5, pp. 296-298).—Abstract of an article in the *London Fruit Grower*. It is a polemic against the commonly accepted canons of fruit-tree pruning. Removal of wood growth in such quantities as usually practiced is believed to be devitalizing. Superfluous growth should be pinched out as soon as it appears. If any is overlooked, it should be cut in the winter months of the year in which it first grew and all weak young branches should be cut back at the same time.

The hardy fruit garden, C. HERRIN (*Gard. Chron.*, 3. ser., 25 (1899), No. 639, pp. 182-183, figs. 8; *Amer. Gard.*, 20 (1899), No. 224, pp. 260, 261, figs. 8).—Detailed directions for performing the operations of crown grafting, saddle grafting, side grafting, and whip grafting. An improved method of crown grafting is figured.

Some notes on cherries in Vermont, F. A. WAUGH (*Amer. Gard.*, 20 (1899), No. 220, pp. 177-179).—Notes on a cooperative experiment with hardy cherries, mostly Russians, in Vermont. Reports on the cherries "were more full, complete, and favorable than those on apples, pears, or plums" distributed at the same time. Two explanations of this fact are suggested: "First, the cherries have thrived better under the varied methods of neglect under which they have fallen and, secondly, there are more good things among the Russian cherries than in any other class of Russian fruits." Many of the varieties have made a very favorable impression throughout the State. Descriptive notes are given of 16 varieties.

The lemon and lemon growing, T. J. ASHBY (*California Fruit Grower*, 24 (1899), No. 11, p. 4).—Brief historical and cultural notes.

The orange, W. J. ALLEN (*Agr. Gaz. New South Wales*, 10 (1899), No. 2, pp. 154-162, pls. 4).—Detailed cultural directions.

The currant vine in South Australia (*Gard. and Field*, 24 (1899), No. 10, pp. 256-258, figs. 5).

A fertilizer for strawberries (*Belg. Hort. et Agr.*, 11 (1899), No. 6, p. 84).—The following fertilizer mixture is said to give very satisfactory results: 500 gm. nitrate of soda, 500 gm. sulphate of ammonia, 3 kg. superphosphate of lime, 2 kg. plaster, 2 kg. sulphate of iron. Apply the mixture in the spring at the rate of 200 to 300 gm. per square meter.

Vanilla planifolia, G. WYTHES (*Gard. Chron.*, 3. ser., 25 (1899), No. 641, p. 213, fig. 1).—A gardener's method of procedure to secure a good crop of vanilla pods.

Landscape gardening for factory homes, W. H. TOLMAN (*Review of Reviews*, 19 (1899), No. 111, pp. 441-444, figs. 6).—An article relating how a manufacturer ornamented his factory grounds, and the means by which interest in landscape gardening was aroused in the factory operatives. The result was a general ornamentation of home grounds in the vicinity and the organization of a local improvement association. The factory people are now more contented and the value of real estate in the neighborhood has been enhanced.

Roadside treatment—actual and possible, Mrs. F. H. TUCKER (*New England Florist*, 5 (1899), No. 7, p. 74).—A lecture before the Massachusetts Horticultural Society.

Naturalizing daffodils, E. BURRELL (*Gardening*, 55 (1899), No. 1489, pp. 234, 235).—Soil, not situation, is considered the important factor in the naturalization of daffodils. A deep sandy loam, with no suspicion of clogging or water logging, is considered best. If the soil is favorable, daffodils will thrive in any exposure, though a northwest aspect with very light soil is most desirable.

What is a cactus dahlia? H. F. BURT (*Amer. Gard.*, 20 (1899), No. 224, pp. 257, 258).—Dahlias are divided, according to the shape of the ray, into three types, one of which is the cactus dahlia. This type is distinguished from the others by three fundamental characters, which are given.

Freesias, F. A. WAUGH (*Gardening*, 7 (1899), No. 157, pp. 196, 197, fig. 1; *Amer. Florist*, 14 (1899), No. 569, pp. 1178, 1179, fig. 1).—Suggestions for simplifying the confusing nomenclature of these flowers, and notes upon their amelioration.

Walls made of ashes and cement for solid beds, E. LONSDALE (*Amer. Florist*, 14 (1899), No. 567, pp. 1117, 1118; *Gardening*, 7 (1899), No. 159, pp. 235-237).—A cheap method is described of constructing the walls of greenhouse beds. Brick may be replaced by a material composed of 6 to 7 parts of anthracite coal ashes and 1 part good Portland cement, the top being finished off with a mixture of 2 parts of sand to 1 of cement.

FORESTRY.

A sketch of the original distribution of white pine in the lower peninsula, C. F. WHEELER (*Michigan Sta. Bul.* 162, p. 5, map 1).—In the lower peninsula of Michigan the white pine is said to have been generally distributed north of the forty-third parallel, although the actual southern limit of lumbering does not conform to this line. In 1835 it was said that the standing pine was estimated at 150,000,000,000 ft. In 1880, as reported by the census report for that year, the merchantable timber in the lower peninsula was estimated at 29,000,000,000 ft. and the total cut for that year was estimated at a little over 4,500,000,000 ft. The latest estimate of the standing white pine was made by the State Commissioner of Labor in 1896, in which it is shown there were approximately 775,000 acres of white pine still standing in the forests of Michigan.

The present condition of Michigan forest and stump lands, with suggestions as to their care, F. C. SKEELS (*Michigan Sta. Bul.* 162, pp. 7-12, map 1, fig. 1).—The present condition of the original forests of Michigan as stated shows that fully 90 per cent of all wooded lands in the State are owned by private parties who will convert the timber into merchantable forms as fast as the market will receive it. Much of the timber in these forests is said to be already past its prime, and it is thought that if the large owners could be interested in the proper cutting of the forests much good could be accomplished. In the maintenance of the present forests two things must be combated, timber thieves and forest fires. In order to accomplish this, legislation will be necessary whereby wardens will be provided for the protection of forests and stump lands. It is also thought that some means should be adopted to influence the owners of stump lands to deed them back to the State, which should have charge of the reforesting of these lands.

Government forests and their preservation, B. HERMAN (*Forester*, 5 (1899), No. 4, pp. 76-79).—A brief account of the extent of the forest reserves and the means employed to preserve them.

Foreign trees for the German forests (*Oesterr. Forst. u. Jagdw. Ztg.*, 17 (1899), No. 10, pp. 73, 74).—Notes are given on a number of American and Japanese forest trees.

Forestry in the State of Washington, K. LUDOFF (*Ztschr. Forst. u. Jagdw.*, 31 (1899), No. 3, pp. 166-171).—Notes are given on the extent and character of the forests of the State.

The relation between forestry and geology in New Jersey, A. HOLLICK (*Amer. Nat.*, 33 (1899), No. 387, pp. 1-14, map 1).

Trees for rocky soils, S. M. MEEHAN (*Florists' Exchange*, 11 (1899), No. 6, p. 128).—Notes on trees particularly easy of cultivation in high latitudes and on stony grounds, and the distinctive merits of each in landscape planting. Trees recommended include all the birches, especially the European birch (*Betula alba*) and varieties, the paper birch (*B. papyrifera*), the poplar birch (*B. populifolia*), sweet birch (*B. lenta*), yellow birch (*B. lutea*), dwarf birch (*B. pumila*), American and European hornbeam, catalpa (*C. speciosa* and *C. bignonioides*), and pines.

The larch, A. CIESLAR (*Centbl. Gesam. Forstw. Wien*, 25 (1899), No. 3, pp. 99-117, figs. 6).—The value of larch as a forest tree is discussed and some of the difficulties experienced in its management are pointed out.

The nitrogen requirements of forest trees, M. I. DUDAN (*Oesterr. Forst. u. Jagdw. Ztg.*, 17 (1899), No. 12, pp. 89, 90).

Investigations on the preservation of oak timber against worms, E. MER (*Compt. Rend. Acad. Sci. Paris*, 127 (1898), No. 26, pp. 1252-1255).—The ringing and decorticating of tree trunks in the spring of the year previous to felling them is recommended. This action brings about the resorption of starch and deposition of tannin in the wood and consequently the timber is less liable to attack.

Forestry legislation, C. D. SMITH (*Michigan Sta. Bul.* 162, pp. 32-39).—The author reviews the various forestry laws of Michigan and briefly summarizes the more recent legislation relative to forestry in the other States.

Methods of reforesting pine stump lands, W. J. BEAL (*Michigan Sta. Bul.* 162, pp. 13-17, fig. 1).—Popular notes are given on the methods of replanting or reforesting the stump lands and suggestions given as to what species would be most desirable to plant.

SEEDS—WEEDS.

Seed-testing regulations (*Landw. Vers. Stat.*, 50 (1898), No. 3-4, pp. 317-321).—The rules governing seed testing, adopted by the Association of Agricultural Experiment Stations in the German Empire at an extraordinary session held in Berlin, January 17, 1898, are given in full. The rules relate to the size of sample, method of sampling, size of test sample, genuineness, purity, absolute weight, volume, milling qualities of cereals, and germination, with special regulations relative to beet and grass seeds.

The regulation relative to disputed determinations was modified as follows: In case of dispute, a sample of the seed is to be sent to the experiment station at Tharand. Here three similar samples are taken and sent without intimation as to origin to three different seed laboratories within the association. The reports from these three stations are submitted to a special committee, which, without knowing anything about the origin of the seed or stations testing them, renders a decision which shall be final.

On the salt-water method of the selection of seeds, T. YOKOI (*Imp. Univ. Col. Agr. [Tokyo] Bul., Vol. 3, No. 5, pp. 121-139*).—The method of selecting seed by specific gravity is said to have been practiced in China and Japan for more than 250 years. The author shows by a number of experiments that there is no constant relationship between the specific gravity and absolute weight of seed, owing to a number of factors, such as the varying quantity of fat, ethereal oils, water, free air, etc. It is also shown that the specific gravity is not an index of the actual amount of nutriment for the nourishment of a plantlet from a seed. A series of experiments with barley is quoted in which seed of the same specific gravity, but of different weights, and those having the same weight but different specific gravity, were compared. It appeared that seed having the greatest absolute weight produced larger plants than those of the highest specific gravity, showing that the absolute weight of the seed has an intimate relation to productive power, but the productive power has little or no relation to specific weight.

A method of selection by the use of salt solutions is described, in which different strengths of solution are employed for different kinds of seed. The results obtained by this method, though not scientifically accurate, are said to be much more satisfactory than the ordinary specific gravity tests, and the method is quite widely employed in Japan.

On the selection of rape seed, C. KOBAYASHI (*Imp. Univ. Col. Agr. [Tokyo] Bul., Vol. 3, No. 5, pp. 140-168*).—Investigations were conducted to ascertain the relation between the absolute weight and specific gravity of rape seed, the relation between the absolute weight and specific gravity of the seed and their germination, and the relation between the specific gravity of rape seed and their oil content. Briefly summarized the conclusions are that seeds of medium specific gravity have a more regular shape, are large, plump, heavy, and consist mainly of the heavier seeds when compared with those having either maximum or minimum specific gravity. The relation of the specific gravity and absolute weight of rape seed to germination shows that seeds of medium specific gravity are always superior in their germinating capacity, and produce more vigorous seedlings than those having a much higher or lower specific gravity. Heavy seeds produce larger seedlings than lighter ones, and if the seed of a given variety of rape be divided into groups according to specific gravity and absolute weight, on the whole, that of medium specific gravity is best for sowing. In estimating the oil content of rape seeds, those having medium specific gravity were found richest in oil.

On the effect of soaking rice seeds, T. YOKOI (*Imp. Univ. Col. Agr. [Tokyo] Bul., Vol. 3, No. 5, pp. 169-173*).—Attention is called to the loss in the dry weight of seeds, caused by soaking them in water for varying periods of time. A number of experiments are quoted in which it is shown that soaking seed for 24 hours entailed losses of from

1.05 per cent for maize to 13.22 per cent for flaxseed. It is further stated that maize and barley soaked for 30 days at 18° C. lost 33.7 and 27.12 per cent, respectively, of their dried weight. The author states that, notwithstanding the injurious effects of soaking seeds, the Japanese farmers are accustomed to soak their rice seeds for a number of days, generally from 3 weeks to, in some cases, 100 or more days before planting. The effect of this soaking for a long time on the germination of seed is noted, and it is said that 120 days' soaking destroys, even in favorable cases, 20 or 30 per cent of the seeds, and those surviving germinate with difficulty. Experiments were conducted in which rice seed was soaked in pure water for 100 days, after which the seed was dried and found to have lost 12.018 per cent of its dry matter. This loss is distributed as follows: Organic matter 11.955, composed of nitrogenous material 1.696 per cent and nonnitrogenous 10.259 per cent, and ash 0.063 per cent. Attention is called to the fact that in the water in which the seed has been soaked for this length of time a very small number of bacteria was to be found, the water remaining remarkably clear and not showing any discoloration, such as is usually found after soaking seed for a much shorter period.

The influence of ether upon the germination of seeds and spores, C. O. TOWNSEND (*Proc. Amer. Assoc. Adv. Sci.*, 17 (1898), pp. 409, 410).—In order to determine the effect of ether upon the germination of seeds and spores, seeds soaked for 24 hours in pure water were transferred to a series of air-tight damp chambers holding 1 liter and containing, respectively, 1, 2.5, 5, and 10 cc. of ether dissolved in 100 cc. of water. The customary checks were maintained for comparison. It was found that 1 cc. of ether hastened the processes of germination slightly, but the subsequent growth of the seedlings was somewhat retarded. In those chambers containing 2.5 and 5 cc. of ether germination was considerably retarded, and an atmosphere containing 10 cc. prevented seeds from germinating. If seeds were removed from this strong atmosphere of ether at the end of from 7 to 10 days and placed under favorable conditions they germinated as readily as if they had not been placed in the ether atmosphere. On the other hand, if the seeds remained in the strong atmosphere of ether 2 weeks they seemed to lose their vitality. Similar results were obtained by placing spores upon plates of gelatin containing 10 cc. of sugar and placing the plates in a chamber containing ether vapors.

Weeds of cornfields, L. H. PAMMEL (*Iowa Sta. Bul.* 39, pp. 25-52, pl. 1, figs. 38).—Various classifications of weeds are given, based upon their origin and duration. The most serious weed pests in the cornfields of Iowa are the foxtail grasses, the bindweed (*Convolvulus sepium*), nut grass, and, in wet soils, the purple smartweed (*Polygonum mihlenbergii*). Of these, the foxtail grasses are the most troublesome. Descriptions are given of the most conspicuous weeds, together with maps showing their distribution throughout the State. Notes are given on the general treatment of cornfields for the eradication of weeds and some specific directions for destroying certain species.

Seed dispersal, W. J. BEAL (*New York: Ginn & Co., 1898, pp. 90, figs. 63*).—This handsome little book contains accounts of how various plants migrate through their adaptive arrangements for seed dispersal.

Absorption of water by rice seed, H. ANDO (*Imp. Univ. Col. Agr. [Tokyo] Bul., Vol. 3, No. 5, pp. 474-478*).—In order to ascertain the amount of water necessary for germination and the length of time required for rice seeds to absorb a sufficient quantity for their germination, the author conducted a series of experiments, from which it appeared that on the average 22.57 per cent of water by weight is required to saturate rice seeds, and this quantity of water is absorbed in 240 hours at a comparatively low temperature. This amount of water is said to be much more than sufficient for germination, and from the experiments it appears that soaking the seed for from 5 to 7 days is sufficient for them to absorb enough water to facilitate their germination.

The field mustard (*Sinapis arvensis*) and its destruction, G. STAES (*Tijdschr. Plantenziekten, 4 (1898), No. 2, pp. 31-35*).

New South Wales weeds, J. H. MAIDEN (*Agr. Gaz. New South Wales, 9 (1898), No. 12, pp. 1371-1374, pls. 2*).—Notes are given on *Cyperus rotundus*, or nut grass.

A new weed on western ranges, L. H. DEWEY (*Erythra, 7 (1899), No. 1, pp. 10, 11*).—The presence of *Molucella laris* on ranges in Oregon and Arizona is noted. The plant is an annual and stock will not eat it, hence it may become a troublesome weed.

Destruction of noxious weeds (*Queensland Agr. Jour., 1 (1899), No. 2, pp. 149, 150*).—Notes the use of iron and copper sulphates for the destruction of charlock and other weeds, and states that extensive experiments with these fungicides are to be conducted at Newcastle-on-Tyne.

DISEASES OF PLANTS.

Mycological notes, B. D. HALSTED (*Bul. Torrey Bot. Club, 26 (1899), No. 1, pp. 12-20, figs. 2*).—The author gives miscellaneous notes on a number of fungi, their influence upon their hosts, etc. He reports the presence during the month of May of a remarkable development of *Botrytis vulgaris* on garden peonies. The outer leaves of the plant were in a healthy condition, while all the inner ones were brown, lifeless, and overgrown with the fungus. A long-continued period of rainy weather preceding the discovery of this attack is thought to have had some influence upon the severity of the attack.

A rust of *Phlox subulata* is reported as quite abundant in the vicinity of New Brunswick, New Jersey. This rust is specifically different from *Puccinia plumbaria*, which is found abundant on *Phlox divaricata* and other species, but it agrees closely with *Puccinia gilva*, a well-known western form.

Attention is called to the effect of sunlight on the development of leaf blight of cherry. Figures are given in which it is shown that the part of the leaf receiving the greatest illumination was most severely affected, and it is stated that possibly the exposure of the leaf to an excess of light brought about a scalding or browning of the tissue, and this in turn might prepare the way for better entrance of the fungus.

The influence of fungi on the fruitfulness of the host plant is shown in the effect produced by asparagus rust upon its host. It seems that the attacks of the fungus weaken the plant materially, reducing the

size of the autumn growth. The production of berries was very small, nearly all the plants appearing as if they were staminate. This exception to the general rule, that when the life of an individual is in danger there is an attempt to reproduce by seed, does not seem to arise so much from the rust actually blighting the flowers, but the flowers did not form, and in the great majority of plants there was no sign of reproduction.

An account is given of fatal poisoning by eating *Amanita phalloides*. The mushrooms were collected and eaten by mistake for innocuous forms.

Observations are recorded which tend to show that one fungus may develop in its host immunity from the attacks of another. Thus the common rust (*Puccinia mamillata*) of climbing smartweed was nearly always absent from those plants which were infested with *Ustilago anomala*. The same thing was found to be true in case of smutted specimens of *Panicum sanguinale*, the leaves of which are rarely affected with *Piricularia grisea*, while the normal plants have the foliage quite generally spotted with it. It is further stated that while fruiting radishes are frequently attacked by *Peronospora parasitica*, and others close at hand by *Cystopus candidus*, it is seldom that both fungi occur on the same individual.

The author points out the effect of fungi on the autumn coloration of foliage, stating that the common maple mildew (*Uromyces circinatus*) causes the presence of green spots in the otherwise highly colored foliage of autumn.¹

A late growth of the bean mildew (*Phytophthora phaseoli*) is reported, in which the fungus is said to thrive upon the pods after the plants have been killed by frosts.

Mycological notes, B. D. HALSTED (*Bul. Torrey Bot. Club*, 26 (1899), No. 2, pp. 72-78).—A number of miscellaneous notes are given of observations and experiments made by the author at the New Jersey Experiment Station. Among the more important is an account of the use of lime for the prevention of club root of turnips. Five years' experiments, in which air-slaked lime had been placed on the soil at the rate of 150, 75, and 37½ bu. per acre, are reviewed. The yield of sound and diseased turnips for the different seasons is given, showing that the larger amount of lime nearly prevented the development of the club-root fungus. On the untreated plats its presence was quite evident, as seen by the large proportion of clubbed roots. The author states that from the tests of 5 years it seems probable that 35 bu. of lime per acre is ample to keep club root from land even when a susceptible crop is grown continuously.

The artificial introduction of onion smut (*Urocystis cepulae*) was investigated. In the experiments, smut-infested soil was added to open rows before any seed was sown. Two varieties were grown in alternate

¹This phenomenon has been previously noted by Waite in Burrill and Earle's Parasitic Fungi of Illinois, pt. 2, p. 409.—Ed.

rows, but there seemed to be no difference in the susceptibility of the different kinds. No smutted onions were found outside of the inoculated belt, while it was abundantly present where the soil had been artificially transferred.

The use of beet leaves as tests for fungicides is commented upon, and the author states that the experience of 5 years leads him to conclude that the beet is one of the most suitable plants with which to experiment with fungicides, and of the different forms of beet the Swiss chard is one of the greatest value. Tests made upon Swiss chard in which Bordeaux mixture and soda Bordeaux were used indicate that the latter fungicide was somewhat more efficient in preventing the leaf blight. This fungicide is made according to the following formula: Caustic soda 1 lb., copper sulphate 3 lbs., lime 5 oz., water 30 gal. It has the advantage of Bordeaux mixture in the greatly reduced amount of lime and consequently in the greater ease with which it may be applied.

Brief notes are given on the susceptibility of bush beans to blight. Since 1894, 2 crops a year have been grown upon the same plat, using a number of varieties. Upon old land the Refugee proved the most productive and Flagolet the least, but in the proportion of spotted pods the results were reversed.

A brief account is given of investigations conducted upon sweet corn, in which it is stated that there was unmistakable evidence of the bacterial disease *Pseudomonas stewartii*, on the variety "First of All." Smut was also quite common in the same variety.

The value of rotation of crops in preventing plant diseases was strikingly shown by the writer in experiments with eggplants. One plat had been grown with this crop 3 successive years, and the crop of half of this plat was compared with that of another on which these plants had not been grown. There were five times as many sound fruits upon the new as upon the old land, and the decayed fruits were only 16 per cent on the new land as compared with 61 per cent on the old.

Observations have been continued on the use of sulphur as a remedy for potato diseases, and three sets of experiments are reported in which, on different years, sulphur was added to the soil in amounts ranging from 120 to 720 lbs. per acre. The seed potatoes in these experiments were treated with corrosive sublimate before planting and comparisons were made with them grown in sulphur treated soils and those receiving no fungicides. As indicated by the experiments, sulphur was efficient in greatly reducing the amount of potato scab, the average results of the different experiments showing a reduction of from 65.1 to 24.27 per cent.

Cotton rust, F. S. EARLE (*Alabama College Sta. Bul. 99*, pp. 281-309).—This disease is primarily due to physiological causes, which reduce the vitality of the plant so as to admit of the active growth of various fungi, of which the principal are *Macrosporium nigricantium*, *Alternari* sp., and *Cercospora gossypina*. It is largely confined to the

older cotton-growing States and prevails over considerable portions of North Carolina, South Carolina, Georgia, Alabama, and Mississippi. It is usually worse on old, worn, sandy lands, but may appear on any soil in which the humus has become exhausted. Plants on low, wet lands and seepy hillsides are also subject to the disease, while sporadic cases may be found in almost any soil under favorable conditions.

Experiments with this disease have been conducted at the station farm and also in cooperation with a number of planters, in which the efficacy of improving the soil by means of potash fertilizers has been tested with good results. From the different experiments it seems that by ameliorating these conditions, giving better drainage, incorporating more vegetable matter in the soil and supplying abundant plant food in complete fertilizers, especially those rich in potash, the disease may be almost wholly prevented. The author believes that by a greater diversification, so that crops will be grown in rotation, the condition of the soil will be improved to such an extent that the disease will be no longer troublesome.

The potato disease, H. M. WARD (*Ann. Bot.*, 12 (1898), No. 48, pp. 561-561).—A potato disease which is not due to *Phytophthora*, and which has often been ascribed to bacteria, has been recognized here and there in England for a number of years, and for 2 years the author has conducted investigations on it. On the diseased plants the shoots turn yellow and die prematurely during the summer before the tubers have become anything like full grown. The disease starts from below and not from the leaves. The roots are few and soon rot away. The tubers do not mature and frequently rot in the ground. The leaves turn yellow and wither on the stems, with symptoms of premature wilting, and often remain hanging on the yellow, glassy-looking, but still living stems. In severe cases, especially in wet places, the stems and roots may all be rotted by the end of July, and casual observation would attribute as a cause the presence of *Phytophthora*. In mild cases the symptoms are not so obvious and the disease may be complicated by the presence of the *Phytophthora* fungus. In advanced stages of the disease the stems either dry up or rot on the wet ground. Very often bacteria gain access to the tissue at a comparatively early stage.

Sections across the lower part of the stem show one or more of the vascular bundles yellowish brown and the principal vessels contain branched septate hyphae. In several cases these hyphae have been traced from the leaves through every internode of the stem through the roots and into the tubers. In advanced cases the brown vessels are stopped with a yellowish gumlike substance. Those tubers which are not attacked while still very young, but which have begun to fill with starch, may offer considerable resistance to the invasion of the fungus; but eventually the vascular strands show the red or yellowish brown color, and in many cases the ripened tubers are to all appearances sound except for microscopic reddish spots at the point of

entrance of the vascular bundles. If gathered and stored dry during the winter but little change will take place in the tubers, but if stored wet various kinds of rot may attack them, the fungi living as saprophytes on the stored reserve.

The author states that this fungus leads the way for a number of purely saprophytic forms, and the evidence seems to show that the parasite is planted with the tubers. On this account the potato grower must exercise care in the selection of his seed and the preparation of his ground. In a subsequent paper the author intends treating the subject at greater length and expects to show that allowing the young shoots to lie in contact with the soil or manures is a possible means for spreading the disease. The same applies to wet soils and situations, and the disease is said to be particularly liable to increase when wet, cold weather follows early growth.

Diseases of the tomato, P. H. ROLFS (*Florida Sta. Bul.* 17, pp. 115-153, pls. 2).—This bulletin treats of some of the more important diseases that have been observed to attack the tomato in Florida.

The rust, black rot, spot, or black spot, due to *Macrosporium solani*, is figured and described. As a preventive remedy thorough spraying with Bordeaux mixture is recommended, at least two applications to be given the plants in the seed bed and the number of sprayings in the field varied with the conditions of the weather.

The bacterial blight of tomato (*Bacillus solanacearum*) is briefly described, the principal characters together with the treatment being largely drawn from Bulletin 12 of the Division of Vegetable Physiology and Pathology of this Department (E. S. R., S. p. 895).

Experiments are reported in which the effect of fertilizers on this blight was tested, from which it appeared that while healthy, vigorous growing plants seemed to show the effects of the blight less quickly than the small, stunted ones, both ultimately succumbed to the disease. Different forms of potash and nitrogen were tested, but no single form seemed to be superior; bone phosphate was found no better than acid phosphate. A fertilizer which would tend to produce a strong, woody stem would be slightly better than one producing a rapid, succulent growth. The relation of different varieties to this blight was investigated and there seems to be some difference in susceptibility. Considerable advantage may be obtained in having the plants as widely separated in rows as possible, as this will tend to prevent the rapid spread of the disease.

A fungus blight of the tomato has been under investigation for about 6 years, but the conditions do not yet warrant the classification and identification of the organism present. When the plant is affected by this disease a single leaf may be observed to droop as though from want of moisture. Later it may regain its normal appearance, to resume its wilted condition in a day or so. In severe cases the whole plant may be affected in this way. A plant once affected rarely recovers, and

those varieties which have hard, woody stems are less susceptible than the succulent ones. Pouring fungicides, such as potassium sulphid, ammoniacal copper carbonate, or eau céleste, about the plants will tend to the suppression of this disease, as the principal portion of the life of the fungus is spent underground.

Notes are given on leaf blight, damping off, and the tomato worm, with suggested remedies for each.

A disease due to *Phytoptus calcladophora* is described. This mite appears to be confined, in the United States, to Florida, though doubtless the same disease has been reported from Spain and Italy. The mites attack the growing bud of the plant and later the fruit buds, causing white hairs to grow out from the epidermis, giving the plant a peculiar ashy white appearance in the affected parts. Applications of sulphur in the form of spray, such as recommended for the rust mite of the orange, or the sprinkling of the plants with flowers of sulphur have been found to be very efficacious.

Root knot, due to *Heterolera radlicicola*, is briefly described, and when present the vines, after bearing, should be collected and burned and some other crop grown on the soil for a year or more.

Considerable loss has been reported due to the dropping of fruit buds from the vines. The causes have been investigated to some extent, and it was found due to partial arresting of the vegetative functions of the plants as well as the lack of fertilization. Another cause, which is capable of being controlled, is too great vegetative growth, and this can be prevented by topping the plants.

Tomato plants are reported as frequently suffering from what is described as hollow stem immediately after being set out from the seed bed. Plants so affected make little or no growth. The causes which produce this trouble are stated to be highly nitrogenous soil in the plant bed, an abundance of water to make the fertilizers quickly available, a quick-growing variety of tomatoes, transplanting without hardening off, and planting into a dry soil necessitating the use of water. The author states that several of these causes acting in conjunction will produce the disease. Its prevention is quite obvious from the causes to which it is attributed.

The stem-rot diseases of the carnation, F. C. STEWART (*Bot. Gaz.*, 27 (1899), No. 2, pp. 129, 130).—The author states that at least two distinct diseases of carnations have been confused under the names "stem-rot" or "die-back." One is caused by *Rhizoctonia*; the other is due to a *Fusarium*. Both diseases are said to be common in the field and greenhouse. The *Fusarium* attacks chiefly the stem and larger branches, discoloring the wood and killing the cortex, but rarely causing a soft rot. The affected plants die gradually with yellowing or drying foliage. The fungus rarely fruits on the outside of the stem, but does so frequently in the cambium and pith of stems which have long been dead.

The *Rhizoctonia* causes the plants to wilt suddenly by rotting the

stem at or just below the surface of the soil. The cortex separates readily from the wood, the pith is attacked quite easily, becoming water-soaked in appearance and filled with hyphæ.

Penicillium as a wood-destroying fungus, H. M. WARD (*Ann. Bot.*, 12 (1898), No. 48, pp. 567, 566).—Spores from pure cultures of *Penicillium* were sown on sterilized blocks of spruce wood cut in March and were found to grow freely and develop large crops of spores. Sections of the infected wood show that the hyphæ of the mold entered the starch bearing cells of the medullary rays, consuming the whole of the starch. In cultures 3 months old the hyphæ were seen deep in the wood, passing from tracheid to tracheid through the bordered pits. Control sections, kept side by side with the others but not artificially inoculated, showed no trace of the mold. On account of the common occurrence of this fungus and its well known resistance to fungicides it must be considered an important destroyer of timber.

Nematode worms, G. E. STONE and R. E. SMITH (*Massachusetts Hatch Sta. Bul.* 55, pp. 67, pls. 12, figs. 2).—After describing the symptoms of nematode injuries, comparisons between the galls caused by nematodes and those of club roots, leguminous tubercles, insects, etc., the authors give in considerable detail descriptions of the parasitic gall-forming nematode, *Heterodera radicola*. The life history of the different forms of this nematode are described, from which it appears that the young worms come into the soil from previously infected plants and wander about until they find roots suitable to their attacks. Forcing their way into the younger portion of the roots they embed themselves in its tissues, and this irritation causes an abnormal development of the root. The worms increase in length and much more in diameter, assuming a spindle and afterwards a club shape. The females continue this swelling process until they have the shape of a gourd and are of a size just about visible to the naked eye. By this time they are mature and after being fertilized produce eggs. The life period of the female is said to be about 6 weeks. The male worms do not remain in the swollen form but after about 4 weeks from the period of entering the root they change into a slender worm-like form which enables them to move about and seek the females with which they copulate, and then perish. While the worms are developing the abnormal growth of the root continues and results in the gall-like swelling or enlargement and such a disarrangement of the tissues that the progress of the sap through the plant is hindered.

An historical review is given of some of the earlier literature relative to this pest and the identity of the species is discussed. The authors think that *H. radicola* and *H. schachtii* are probably one and the same species.

The second part of the bulletin treats of the economic consideration of the subject relative to means for controlling these pests. In northern United States the greatest amount of injury done is to plants in

greenhouses, although not infrequently outdoor plants are subjected to nematodes by being brought into contact with infested earth or manure. At the station it was found that the eggs will not survive the winter. The various means which were tested for destroying the adult worms are reviewed at some length. The use of chemicals for this purpose is of no practical value. While there are many chemicals which will kill the adult worms yet the most effectual, complete, and practical method for exterminating nematodes in greenhouses is by sterilizing the soil by means of steam. This is best effected under a steam pressure somewhat in excess of 50 lbs. The minimum amount of heat necessary to kill nematodes and eggs when found in the soil is about 140° F., but, for all practical purposes, it was found desirable to make use of higher temperatures ranging from 180 to 212° F. This steam sterilizing of the soil, in addition to destroying the nematodes, killed many other greenhouse pests, greatly improved the mechanical condition of the soil, and rendered the humus compounds more available for plant food, which resulted in giving the plants a considerable acceleration in their rate of growth.

Investigations on means for increasing adherence of fungicides, J. PERRAUD (*Compt. Rend. Acad. Sci. Paris*, 127 (1898), No. 22, pp. 876-879).—In order to ascertain the degree of adherence of a number of fungicides, the author conducted a series of experiments with a solution of 2 per cent copper sulphate rendered slightly alkaline with fat lime, 2 per cent copper sulphate and 2 per cent fat lime, 2 per cent copper sulphate rendered slightly alkaline with slaked lime, 2 per cent copper sulphate rendered slightly alkaline with sodium carbonate and neutral copper acetate. To these different solutions a number of substances were added to render them more adherent. Among those used were dried blood, the white of egg, gum tragacanth, glue, starch, dextrin, potassium silicate, molasses, aluminum sulphate, soap, and resin. Eau celeste was also tested. After spraying these upon grape leaves and fruits and allowing them to dry for 2 hours in the sun, both the fruit and leaves were subjected to an artificial rain amounting to 4 mm. and the percentage of copper adhering to them determined. The results show that all the modern fungicides are less adherent to the fruit of the grape than to the leaves. From the standpoint of their adherence the fungicides tested are reported in the following order: (1) The solution of copper sulphate made slightly alkaline with carbonate of soda; (2) the copper sulphate solution made slightly alkaline with fat lime; (3) the solution in which equal quantities of copper and lime were used; (4) neutral copper acetate; (5) eau celeste and (6) copper sulphate and slaked lime.

Of the substances used to increase the adherence of the fungicides, resin was by far the best, followed by soap, potassium silicate, molasses, gum tragacanth, and glue. The other substances employed either were without apparent effect or seemed to diminish the adherence of the fungicides. It is ascertained that the nature of the lime which enters

the preparation of Bordeaux mixture is of great importance. Quick lime only should be used, and it should be slaked at the time of using. On account of the remarkable adherence of resin mixtures, especially on the fruit, the author proposes continuing investigations with fungicides containing this substance.

Means for preventing the introduction of plant diseases, J. E. WEISS (*Prakt. Bl. Pflanzenschutz*, 2 (1896), No. 1, pp. 5, 6).

Contributions to the knowledge of parasitic fungi, G. LAGERHEIM (*Vet. Akad. Handl. Bihang K. Srenska*, 24 (1898), No. 4, pp. 2, pls. 3: abs. in *Bot. Centbl.*, 77 (1899), No. 12, pp. 405, 406).—Notes are given on *Cladochytrium alfalfa* n. sp., parasitic on alfalfa, *Empusa phalangicida* n. sp. on insects, and *Iola* (*Cystobasidium*) *lasioboli* n. sp. on *Lasiobolus equinus*.

Apple and pear scab, G. STAES (*Tijdschr. Plantenziekten*, 4 (1898), No. 5, pp. 157-160).—Notes are given on *Fusicladium dendriticum* and *F. pyrinum*, and the use of Bordeaux mixture is recommended for preventing the diseases.

Combating the leaf diseases of fruit trees, P. HELD (*Deut. Landw. Presse*, 25 (1898), No. 92, p. 966).—Brief descriptive notes are given on a number of fungi attacking the leaves of fruit trees and directions for combating them. Bordeaux mixture, copper-soda solution, Burgundy mixture, and sulphur are the fungicides recommended.

A disease of peach trees, J. RITZEMA-BOS (*Tijdschr. Plantenziekten*, 4 (1898), No. 5, pp. 146-154).—Notes are given on *Monilia fructigena*.

A report on the diseases of the chestnut in the Pyrenees, Basque Provinces, Spain, and Portugal, L. CRIÉ (*Bul. [Min. Agr. France]*, 18 (1899), No. 6, pp. 1291-1313).

Studies of the hexenbesen rust of barberry, J. ERIKSSON (*Beitr. Biol. Pflanz.*, 8 (1898), No. 1, pp. 1-16, pls. 3).—Studies on *Puccinia arhenatheri*.

A destructive disease of conifers, DOSCH (*Ztschr. Landw. Ver. Hssen*, 1898, No. 39, pp. 385, 386).

On the appearance of a sereh-like disease of sugar cane, M. RACIBORSKI (*Meded. Proefstat. Suikerriet West Java*, No. 36, pp. 5-10).

The "Dongkellan" disease of sugar cane, M. RACIBORSKI (*Meded. Proefstat. Suikerriet West Java*, No. 36, pp. 1-5).—A description is given of this disease, together with notes on its distribution. It is said to be very distinct from the disease described by Wakker under the same name.

Pestalozzia diseases of seedlings, J. RITZEMA-BOS (*Tijdschr. Plantenziekten*, 4 (1898), No. 6, pp. 161-172, pls. 3).—Notes are given on attacks of *Pestalozzia hartigii* and *P. funerea* on *Pseudotsuga douglasii*, *Chamaecyparis menziesii*, *Biota*, *Cupressus*, *Juniperus*, *Pinus*, etc.

A bacterial disease of the leaves of *Oncidium*, V. PEGLION (*Centbl. Bakt. u. Par.*, 2. Abt., 5 (1899), No. 1, pp. 33-37).—An organism, to which the name *Bacterium oncidii* n. sp. is given, has been isolated and the author claims by his experiments to have demonstrated that it causes a serious disease of these plants which are cultivated to a considerable extent in Italy. The organism is 1.3 to 1.5 μ in length and 0.8 to 1 μ in diameter and is said to grow readily in the more common culture media.

The common parasite of the powdery mildews, D. GRIFFITHS (*Bul. Torrey Bot. Club*, 26 (1899), No. 3, pp. 184-188, pl. 1).—Notes are given of *Ampelomyces quisqualis* parasitic on a number of the powdery mildews. This parasite has usually been referred to under the generic name *Cicinobolus*.

Concerning a parasite of *Lactarius deliciosus*, R. MAIRE (*Bul. Herb. Boissier*, 7 (1899), No. 3, pp. 137-143).—*Hypomyces ruilleminianus* n. sp. is described.

A parasite of *Lactarius torminosus*, R. MAIRE (*Bul. Herb. Boissier*, 7 (1899), No. 3, pp. 144, 145).—*Hypomyces thiryanus* n. sp. is described.

Root swellings of sugar beets, S. STOKLASA (*Centbl. Bakt. u. Par.*, 2. Abt., 5 (1899), No. 3, pp. 95-98).—Two forms of excrescences are recognized, one where the excrescence is joined to the upper or middle part of the root by a constricted growth and

the other a more general outgrowth of the lower part of the root. The first is of rather general distribution, while the other occurs sporadically. These outgrowths are due to several causes, nematodes among others, which interfere with the normal development of the root. In such tissues the sugar content is lowered very considerably over the rest of the root.

On a possible cause of the leaf spot or mosaic disease of tobacco, M. W. BELERINCK (*Centbl. Bakt. u. Par., 2. Abt., 5 (1899), No. 1, pp. 27-33*).—It is claimed that the cause of this disease, and probably that of other plants which have hitherto been unexplained, may be attributed to what the author terms a living fluid contagium.

Chlorosis in plants, G. STAES (*Tijdschr. Plantenziekten, 4 (1898), No. 4, pp. 97-115*).—The possible causes of chlorosis are discussed and means suggested for its prevention. Applications of iron sulphate to chlorotic plants is recommended.

Effects of lightning on the grapevine, L. RAVAZ and A. BONNET (*Prog. Agr. et Vit. (ed. Lest), 20 (1899), No. 13, pp. 392-399, pl. 1, fig. 1*).—Notes the injury to many vineyards in the vicinity of Montpellier and states that many so-called diseases may be due to this cause, the injury preparing the way for numerous fungi and bacteria.

Experiments for the prevention of potato scab, WILFARTH (*Deut. Landw. Presse, 25 (1898), No. 25, pp. 273, 274*).—Experiments with "Sulfarin," a patented article said to be composed of keiserit with 15 per cent of free sulphuric acid, are reported. The powder was applied to the tubers and was efficient in reducing the proportion of scabby tubers, but the yield was also diminished.

On the treatment of seed potatoes with Bordeaux mixture and formalin, G. STAES (*Tijdschr. Plantenziekten, 4 (1898), No. 3, pp. 65-71*).

ENTOMOLOGY.

Proceedings of the tenth annual meeting of the Association of Economic Entomologists (*U. S. Dept. Agr., Division of Entomology Bul. 17, n. ser., pp. 104, figs. 4*).—At this meeting, held in Boston, Massachusetts, August 19 and 20, 1898, the following papers were read:

The duty of economic entomology, H. Osborn (pp. 6-12).—This is the president's address to the Association. The matter is summed up under three heads: (1) Acquisition of knowledge of life and habits and direct remedies; (2) a knowledge of distribution and methods of prevention or control; and (3) education of people to appreciation of this need and to intelligent methods of application.

Two beneficial insects introduced from Europe, L. O. Howard (pp. 13-16, figs. 2).—This gives an account of the importation by the author of *Scutellista cyanea*, a Chalcidid parasite of *Ceroplastes*. The parasite was imported from Italy and has probably been successfully established at Baton Rouge, Louisiana.

The author also relates the accidental importation near Boston of another Chalcidid parasite, *Habrolepis dalmanni*, which attacks the imported scale, *Asterodiaspis quercicola*. The scale seems to be thoroughly established about Boston and the parasite is also present in large numbers.

Notes on some of the insects of the year in the State of New York, E. P. Felt (pp. 16-23).—This paper gives many biological and economic details concerning a number of the more common injurious insects.

The brown-tail moth, C. H. Fernald (pp. 24-31).—It is stated that the moth was first discovered in this country in the spring of 1897 in Somerville, Massachusetts. The center of infestation was in the vicinity of a florist who had imported roses and other shrubs from France and Holland. From the evidence at hand it appears that the brown-tail moth had been introduced as early as 1885. The distribution in this country is confined to a part of Somerville, Cambridge, Everett, Medford, and Malden. A brief account is given of the life history of the moth and of the nettling effects of the hairs of the caterpillar, and the author gives a long list of food plants upon which the caterpillar has been found.

Among its parasites are mentioned *Phaenogenes hebe*, *Diglochis omnivora*, *Euphorocera claripennis*. The Baltimore oriole, black-billed cuckoo, crow blackbird, and English sparrow are also reported as feeding upon the insects. Spraying experiments were tried with arsenate of lead 1 lb. to 150 gal. of water, Paris green 1 lb. to 150 gal. of water, and Scheele's green 1 lb. to 150 gal. of water. Good results were obtained from all 3 insecticides. The author states that the "remedies generally adopted for the brown-tail moth are to cut off and burn the webs during the winter while the young caterpillars are still within them." The Massachusetts legislature has passed a law authorizing the Board of Agriculture to take steps for the extermination of the moth.

The distribution of the San José or pernicious scale in New Jersey, J. B. Smith (pp. 32-39).—A detailed account is given of the present status of the San José scale in New Jersey, and of the three main centers of infestation. In the older infested places the scale is said to have become much reduced in numbers.

Hydrocyanic-acid gas as a remedy for the San José scale and other insects, W. G. Johnson (pp. 39-43).—The author gives a record of experiments with this gas in the laboratory and in the field and concludes "that nursery stock and young trees of 1 and 2 years old to be replanted should be exposed to the gas for 30 minutes or longer, and that from 0.18 to 0.25 gm. of potassium cyanid should be used for every cubic foot of air space inclosed." On large bearing trees 0.20 gm. of cyanid gave the best results.

Some notes on observations in West Virginia, A. D. Hopkins (pp. 44-49).—This article contains brief notes on the following insects: The San José scale (*Aspidiotus perniciosus*), Forbes scale (*A. forbesi*), asparagus beetle (*Crioceris asparagi*), timothy billbug (*Sphenophorus sculptilis*), timothy-leaf miner (*Odontocera dorsalis*), clover-seed chalcidid (*Brucophagus funebris*), rose aphid parasite (*Ephedrus incompletus*), spruce gall mite (*Chermes abietis*), Cerambycid and Buprestid beetles, *Lymerylon sericeum*, *Eupsalis minuta*, and the periodical cicada (*Cicada septendecim*).

Notes on house flies and mosquitoes, L. O. Howard (pp. 55, 56).—This is the author's abstract of an article published as Circular No. 36, 2 ser., Division of Entomology (E. S. R., 10, p. 654).

Pulvinaria acericola (W. & R.) and *P. innumerabilis* Rathv., L. O. Howard (pp. 57, 58).—The author gives grounds for separating the *Pulvinaria* found on maples into the 2 species mentioned.

An abnormal *Coccinellid*, A. F. Burgess (pp. 59, 60).—The paper contains an account of melanism in *Adalia bipunctata*, a number of black individuals occurring in connection with typical specimens.

Notes on some Massachusetts *Coccida*, R. A. Cooley (pp. 61-65).—This contains an account of observations on the maple-leaf louse (*Pseudococcus aceris*), *Aspidiotus forbesi*, *A. ancylus*, *A. fernaldi*, and *Diaspis amygdali*.

Notes on spruce-bark beetles, C. M. Weed and W. F. Fiske (pp. 67-69).—The beetles in question are said to belong to the species *Dendroctonus rufipennis*. In describing the habits of the insect the authors say: "In a space 15 in. long by 5 wide no less than eight burrows were discovered. They were in all stages of development, from a mere hollowing in the bark containing a single beetle, to a tunnel 2 or 3 in. long, and in these cases also there was usually but one inhabitant, though it was not rare even to find the male still accompanying his spouse."

Notes on the life history of the woolly aphid of apple, W. B. Alwood (pp. 70-72).—The author's object in his experiments was to determine the part which the sexual form plays in the life history of the insect, and to study the hibernation of the agamic form.

"Such trouble was experienced in rearing the sexual individual that we were not able to make extensive observations on oviposition, nor were we able to carry eggs over to the hatching period to produce a stem mother, but they were carried long enough to conclude that the egg does not hatch in the autumn. . . ."

"From the long series of observations made, covering nearly 2 years, it is concluded that the sexual form plays a very unimportant part in the propagation and perpetuation of the species in this latitude.

"The agamic individuals are always present, usually in great numbers on the roots and to a less extent on the stems of the apple trees, and these colonies persist, so far as our observations go, and reproduce other agamic individuals in a direct line without cessation and without apparent loss of virility."

On the life history of *Protoparce carolina*, W. B. Alwood (pp. 72-74).—The record kept was for Blacksburg, Virginia. The first moths were observed June 7. The egg laying began June 20 and continued until the middle of July. Four moltings were observed, and the insect was found to be partly double brooded. *Apanteles congregatus* and a species of *Chaetolyga* are recorded as parasites of the larva of *Protoparce*.

Notes on the fertilization of muskmelons by insects, F. W. Rane (pp. 75, 76).—The author states that the perfect flowers of the muskmelon have nearly as much pollen as the staminate ones and that the purpose of the staminate flower seems doubtful. Fertilization by insects is said to be the natural method, but the insects concerned are not named.

Notes on tent caterpillars, C. M. Weed (pp. 76-78).—Heavy spring rains in conjunction with a bacterial disease are said to have destroyed 90 per cent of the larvæ of the American tent caterpillar.

The most abundant insect parasite which came under the author's observation was *Pimpla conquisitor*. It is stated that the forest tent caterpillar (*Clisiocampa disstria*) is gradually becoming more destructive in New Hampshire and is injuring nearly all deciduous shade trees.

Recent work of the gypsy moth committee, E. H. Forbush (pp. 78, 79).—The writer states that the purpose of the committee has been and still is to work from the outer limits of infestation by the gypsy moth toward the central portions. The committee, it is stated, is more hopeful than ever of ultimate success in exterminating the gypsy moth.

The San José scale in Connecticut, W. E. Britton (pp. 81–84, fig. 1).—This paper contains a history of the importation of the scale into the State and an account of its present distribution.

Insect injury to millet, F. H. Chittenden (pp. 84–86).—Two species of flea-beetles (*Chytoenema denticulata* and *C. pulicaria*) are recorded as attacking millet on the grounds of the Department of Agriculture. The larva of a wireworm (*Monocrepidius bellus*) was found in some numbers about the roots of the millet and is recorded as injurious for the first time. The larva of *Diabrotica 12-punctata*, of a species of *Lachnosterna*, and of *Chlorops assimilis* were found injurious to the roots of millet.

Entomological ethics, T. D. A. Cockerell (pp. 87–90).—This paper sets forth the author's ideas of the ethical principles which should govern station entomologists.

Vernacular names of insects, E. W. Doran (pp. 90–92).—This article contains a list of common names of insects written as proposed by C. P. Gillette and as preferred by the author.

Notes from Maryland on the principal injurious insects of the year, W. G. Johnson (pp. 92–94).—The author gives brief details of the life history and remedial treatment of certain injurious insects.

Notes on insecticides, C. L. Marlatt (pp. 94–98).—The writer records results obtained in experiments with pure kerosene, fish-oil soaps, and arsenite of copper. It is concluded that "treatment with oil is dangerous and may kill the trees." The objections to fish-oil soaps are two: (1) The solution is usually gelatinous and difficult to use as a spray, and (2) substances like silicate of soda are frequently used in making these soaps, which destroy their insecticide value.

Insects of the year in Ohio, F. M. Webster and C. W. Mully (pp. 98–102).—The authors give notes on a large number of injurious insects. A report is made of experiments with kaimit to prevent the attack of wireworms. It was found to have no value for this purpose.

Some miscellaneous results of the work of the Division of Entomology (*U. S. Dept. Agr., Division of Entomology Bul. 18, n. ser., pp. 101, figs. 17*).—*The San José scale on dried fruit, L. O. Howard* (pp. 7–13).—On account of the action of the Swiss Government in excluding American dried fruits, some experiments were undertaken to determine whether the San José scale could live through the evaporation and drying processes to which fruits are subjected for exportation. Fruits

were dried by both processes and all San José scale were found dead at the end of the experiment.

A new coccid on birch, H. G. Hubbard and T. Pergande (pp. 13-26).—The article contains an exhaustive technical description of the anatomical characters and of the different developmental stages of *Xylococcus betulae*.

The peach lecanium, T. Pergande (pp. 26-29).—This insect, which has been considered identical with the European *Lecanium persicae*, is shown to be a new species and is described as *L. nigrofasciatum*.

The work against Icerya purchasi in Portugal, with an account of the introduction from America of Novius cardinalis, L. O. Howard (pp. 30-35).—The article gives an account of the successful introduction of the well-known ladybird into Portugal, where it has already cleaned many badly infested orchards.

Twig pruners and allied species, F. H. Chittenden (pp. 35-43).—The habits and life history of *Elaphidion villosum* are given in detail. The article contains also brief notes on *E. inerme*, *E. subpubescens*, *E. mucronatum*, *E. tectum*, *E. cinereum*, *E. irroratum*, *E. unicolor*, and *E. imbellis*.

A destructive borer enemy of birch trees, with notes on related species, F. H. Chittenden (pp. 44-51).—The author relates an attack of *Agrilus aurivorus* upon the European white birch and other species of birch in the city of Buffalo. Correspondents from that city are of the opinion that unless the ravages of this beetle can be stopped all birch trees in the city will be destroyed. A careful description is given of the different stages of the insect and an account of the literature referring to this species.

As means of control the author suggests wrapping the birch trees with paper or covering them with whitewash, or the use of hydraulic cement and skimmed milk of the consistency of thick paint. The author says, "Preventives used should be applied to the trees just before the issuance of the beetles, which may be in some localities at least as early as the latter days of May. If paper wrappings are used, they can be removed as soon as the danger season is past, which will be within two or three months of the time of the first appearance of the beetles."

A new nomenclature for the broods of the periodical cicada, C. L. Marlatt (pp. 52-58).—In this paper the author proposes a new numbering of the broods of the periodical cicada, so as to show more clearly the relationship of the different broods to one another and their sequence in time of appearance. The 17-year races are placed first, and the broods are numbered from I to XVII, inclusive. These are followed by the 13-year races, of which the broods are numbered from XVIII to XXX. Some of these numbers have as yet no broods assigned to them. The grounds upon which this new numbering is based may perhaps best be stated in the author's own words: "As a rule, the relationship of the broods in point of distribution agrees with their kinship as indicated by their sequence in time of appearance. The relationship indicated by the latter, viz, their sequence in time, is doubtless untrust-

worthy as indicating origin, in some instances, on account of the uncertainty arising from the action of the principle of retardation, on the one hand, and acceleration, on the other, in the forming of new broods."

A consideration of the validity of the old records bearing on the distribution of the broods of the periodical cicada, with particular reference to the occurrence of Broods VI and XVIII in 1898, C. L. Marlatt (pp. 59-78).—The author gives the result of an investigation which was undertaken to determine the distribution of Brood XVIII of the 13-year race and of Brood VI of the 17-year race. Circular letters were sent to several thousand correspondents, and from the replies the distribution of these broods has been outlined by counties and localities much more definitely than has heretofore been done.

Some observations on the cycle of the sexual development of the blood louse (Schizoneura lanigera), S. Mokrzetski (pp. 78-81).—This paper contains biological details of the life history and development of this insect, together with notes on the means of transportation of the insect from one locality to another.

A cecidomyiid injurious to seeds of sorghum, D. W. Coquillett (pp. 81, 82).—Seeds of sorghum which were received from the Texas Station were found to be infested by an insect which upon examination proved to be a new species and is described by the author under the name of *Diplosis sorghicola*. In the seeds which the Department received these insects were very numerous, and the only parasite which was noticed upon them was the genus of *Chalcis* flies known as *Apostrocetrus*.

A leaf tier of grape and elderberry, F. H. Chittenden (pp. 82, 83).—The author relates that in the summer of 1897, at Colonial Beach, Virginia, he noticed numbers of the larvæ of a pyralid moth which had the habit of folding the leaves of grapes together and joining them with a sort of web. When reared, the moth proved to be *Phylotenia tertialis*. Later investigations disclosed the fact that the same species lives upon the elder and has the same habit upon that plant. The species is recorded from Maine, New Hampshire, Massachusetts, New York City, Pennsylvania, Onaga, Kansas, and Colonial Beach, Virginia.

A flea-beetle living on purslane, F. H. Chittenden (pp. 83-85).—At Marshall Hall, Maryland, the author found eggs of the flea-beetle which when reared proved to be those of *Disonycha caroliniana*. The larvæ of the beetle feed upon the common purslane, *Portulaca oleracea*. A technical description is given of the larva and pupa. Both the larval and pupal forms are said to resemble very closely another species of the same genus, *D. xanthomelana*.

Cotton-field insects (pp. 85-88).—A correspondent of the Division having set out three trap lanterns for one night near Victoria, Texas, forwarded for examination the insects which were taken. In all the catch contained 24,492 specimens, representing approximately 328 species. The injurious species numbered 13,113 specimens, the beneficial 8,262 specimens, and those of a negative character 3,117 specimens. The object of the experiment was to determine whether the Mexican

cotton-boll weevil could be captured by these traps. Not a single specimen of the insect was found.

Under the caption "General notes" are appended to the bulletin observations of an economic character upon a large number of injurious and other insects, as well as many notes from the various correspondents of the Division in different parts of the country.

Twentieth report of the State entomologist on the noxious and beneficial insects of the State of Illinois, S. A. FORBES (*pp.* 112+XXXII).—The report treats of the San José scale, white grubs, chinch bug, *Odynerus foraminatus*, and a new disease of the army worm. In an appendix to the report, E. L. Sturment gives an account of the white-pine Chermes.

Concerning the San José scale, the author gives a list of its food plants, and an account of the nature of the injuries which are caused by the insect. The means and agents concerned in the dispersal of the insect are discussed at some length. On the authority of Professor Stedman, it is stated that many new colonies have been observed in their incipient stages on branches and twigs which support bird nests. This is interpreted as indicating the instrumentality of birds in the dispersal of the scale. The original home of the insect and its early geographical distribution in the United States are briefly discussed.

The San José scale is said to have been first introduced into Illinois during the period from 1886 to 1891. Twenty-one distinct colonies have been located in Illinois, and of these colonies all which have been definitely traced to their origin are said to have come from nurseries in New Jersey. A detailed description is given of the different infestations. In one of the worst-infested orchards a spraying experiment was tried. Whale-oil soap in the proportion of 2 lbs. to a gallon of water was applied hot. The first application was made in November and a second one late in March. This method proved quite effective, and it was estimated that 99 per cent of the scales were destroyed by the two applications. The appearance of the insect is briefly described and an account of its life history is given.

Among the natural checks on the multiplication of the scale are mentioned certain climatic conditions, predaceous and parasitic insects, and fungus diseases. The most important insect parasites are said to be *Aphelinus fuscipennis*, *Chilocorus bivulnerus*, and *Smilia misella*.

Field notes are also recorded of a remarkable outbreak of white grubs. The species concerned were *Lachnosterna fusca* and *L. hirticula*. The grubs were reported as being unusually numerous about the roots of all field crops except clover, which enjoyed a comparative immunity. Crops on high land suffered more than those on low land, and fields in the vicinity of woodland were more infested than fields which were more distant from timbered areas. A brief life history of the white grub is given, and remedies are suggested, among which may be mentioned the pasturing of infested fields with pigs and the use of clover in the rotation of crops.

Experiments with summer remedies against chinch bugs demonstrated the efficacy of the barrier and post-hole method. To protect a field from the advancing chinch bugs a dust furrow is made along the side of the field. The chinch bugs have great difficulty in crossing a dry dusty furrow and crawl along the furrow to find an avenue of escape. In so doing they fall into post holes, which it is recommended to dig at intervals as traps for the accumulating chinch bugs. A coal-tar line about three-fourths inch broad is said to be as effective as the dust furrow, provided the tar-line be freshened two or three times per day. Salt saturated with kerosene is said to have been quite ineffectual as a barrier.

After an extended discussion of the causes of unusual outbreaks of the chinch bugs, the author observes that—

“As a general result of these investigations, we certainly have no warrant for asserting that the natural agencies effective in reducing an extraordinary outbreak of the chinch bug can now be definitely controlled by us for economic ends. So far as ascertained the final causes of unusual natural destruction of this insect are meteorological; and until the weather of the season, or even of the year, can be foretold with approximate definiteness and certainty, we can not forecast the course of events with respect to injuries by the chinch bug.”

A species of solitary wasp (*Odynerus foraminatus*) is recorded as frequently building its mud nests in the opening for the escape of air from the retaining valve of automatic brakes such as are used on freight trains. As a remedy it is suggested that the passageway from the valve be made angular or slit-like.

An apparently new and undetermined disease is said to have caused great destruction of the army worm. The nature of the disease was not discovered, but one of its most marked peculiarities is said to be the degeneration of the fatty bodies of the caterpillars.

The account of the white-pine Chermes (*Chermes pinicorticis*) includes a list of its food plants, its economic importance, feeding habits, and distribution. Among the natural enemies of the Chermes are mentioned *Syrphus* sp. ? *Chryropa robertsoni*, *Hemerobius alternans*, *Leucopis simplex*, *Chilocorus birulnerus*, and *Megilla maculata*. The only artificial remedy which was tried was kerosene emulsion. It was applied in May and proved very effective.

Thirteenth report of the State entomologist on injurious and other insects of the State of New York, 1897, J. A. LINTNER (*Fifty-first An. Rpt. New York State Mus., 1897, pp. 327-390, pls. 2, figs. 2*).—The red-breasted sawfly (*Tenthredo rufopectus*) is reported as a new currant pest. The larva of this sawfly, unlike the larva of most sawflies, is recorded as having the habit of boring in the stems of currants and of being found in company with the currant-stem girdler in such situations. A brief account is given of the life history and habit of the insect so far as known and of its distribution. As to remedies, “the wilted tips should be watched for in the early spring, and as soon as seen should be cut off a little below the place of injury. If the attack should escape attention till some time after the dropping of the

tips, the cutting should be made a few inches farther down, and beyond the burrow of the larva."

Brief notes are given of the habits of the white-horned Urocerus (*U. albicornis*). The insect was observed depositing its eggs upon the surface of some freshly sawed spruce lumber. It is stated that this species is rather rare in New York; and as it ordinarily deposits its eggs in dead rather than living timber, no great danger is expected to result from it. A systematic table is given for the separation of the various species of Urocerus found in the State of New York.

The author records some notes on the eggs, larval stages, pupal and adult form of the imperial moth. Its distribution is given for the State of New York. As to its natural enemies, it is said to be exceptionally free, no parasites having been recorded for it, though in one instance it is said to have been attacked by house ants.

A popular account is given of the tarnished plant bug (*Lygus pratensis*). It is recorded that it was unusually destructive to young peach trees in New York through its habit of sucking the juices from the developing buds, and thereby stunting the growth of the trees. As remedies, the author suggests the burning of weeds and rubbish which might serve as a shelter for the insects. When they occur in large numbers, they may perhaps be best captured by jarring into a large net.

The author gives brief notes upon the following insects: Clover-hay caterpillar (*Pyralis costalis*), clover-seed midge (*Cecidomyia leguminicola*), carpet beetle (*Anthrenus scrophulariae*), oak pruner (*Elaphidion villosum*), hickory borer (*Cyrtene pictus*), elm-leaf beetle (*Galerucella luteola*), chinch bug (*Blissus leucopterus*), *Pemphigus populi-transversus*, *Chaitophorus* sp., *Callipterus ulmifolii*, *Drepanosiphum acerifolii*, *Aphis mali*, *Myzus cerasi*, *M. ribis*, *Rhopalosiphum* sp., and *Thrips tabaci*.

The report contains a list of all the publications of the entomologist for the current year, together with such additions as have been made to the State collection, and rather exhaustive bibliographies of most of the insects which are treated in it.

Fourteenth report of the State entomologist on injurious and other insects of the State of New York, E. P. FELT (*Bul. New York State Mus.*, 5 (1898), No. 23, pp. 151-295, pls. 9, figs. 20).—The report contains notes on the following insects:

Pale brown Byturus (*Byturus unicolor*) (pp. 158-160).—The beetles are said to have been found in the opening buds of raspberries. According to Fitch the larvæ are found in the berry. The remedies suggested are spraying with arsenites, hand picking, and beating the beetles into pans containing kerosene.

Gooseberry-fruit fly (*Trypeta canadensis*) (pp. 161-163).—The author gives an account of the work of this insect in New York State, with notes on its distribution and life history. For controlling the insect the destruction of the fruit by chickens or artificial means is recommended.

The white-marked tussock moth (*Notolophus leucostigma*) (pp. 163-176,

figs. 4).—The article contains a notice of the unusual ravages of this insect in 1898, together with notes on the life history, habits, natural enemies, and approved artificial remedies, and a synoptic table for the determination of the larvæ of the species of *Notolophus*.

Apple-tree tent caterpillar (*Clisiocampa americana*) (pp. 177–190, figs. 3).—A résumé is given of the food plants, habits, and distribution of the insect, and an account of the well-known remedies for controlling it.

Forest tent caterpillar (*Clisiocampa disstria*) (pp. 191–201, figs. 2).—The insect is said to have been unusually destructive to forest and fruit trees in New York State for the past 2 years. The food plants and natural enemies of the insect are given and the usual remedies recommended.

Zebra caterpillar (*Manestra picta*) (pp. 201–207, fig. 1).—This insect is reported as having caused great destruction to timothy hay and oats. A description of the insect is given, together with notes on the natural enemies and the remedies to be recommended.

Nylina antennata (pp. 207–213, fig. 1).—The caterpillar of this insect is recorded as feeding on soft maples, upon which it was very injurious. A good description of the insect is added. The author reared from the insect a parasite tachina fly (*Winthemia 4-pustulata*). As remedies he recommends spraying with the arsenites, or “many of the descending caterpillars can be killed by inclosing the trunks of the infested trees with a low, overhanging barricade and then treating the collected larvæ with hot water.”

The author records biological and economic notes on the following insects: *Lecanium tulipifera*, *Lepisma domestica*, *Eurypebaa hentzii*, *Eriocampoides limacina*, *Silvanus surinamensis*, *Elaphidion villosum*, *Galerucella luteola*, *G. cavicollis*, an elm-leaf miner, *Lecanium armeniacum*, *L. cerasifer*, and the San José scale.

Under the caption “Hints about insecticides,” the author gives a general account of the substances used for destroying insects and the rationale of spraying.

The report is supplemented with a list of the publications of the entomologist for the year and an exhaustive index.

Report of the entomologist, A. D. HOPKINS (*West Virginia Sta. Rpt. 1897*, pp. 42–57).—The special lines of work carried on by the author are reviewed, and attention is called to certain of the more important features. Special study was made of the scolytid family of beetles, which family contains the most destructive and dangerous enemies of forest and shade trees, as well as of fruit trees, and one of the worst enemies of the red clover. The collection of these insects made under the author’s supervision is said to be one of the most complete in existence.

The series of experiments begun in 1895 to determine the best time to fell timber have been continued and some remarkable results have been obtained, but the author states that in order to verify them and

arrive at definite conclusions they must be continued for some time to come.

A general study of forest conditions and life zones has been begun; and a preliminary report is made of observations on the influence of altitude on the distribution of plant and animal life.

Brief notes are given on investigations made to determine and establish varieties of timothy and red clover and miscellaneous work in investigating the San José scale, inspection of nurseries, the army worm, a parasite of the rose aphid, the maple-twig borer, etc.

Preliminary report upon the insect enemies of tobacco in Florida. A. L. QUAINANCE (*Florida Sta. Bul.* 48, pp. 150-188, figs. 16).—The bulletin treats of the following insects which are injurious to tobacco:

The horn worm or tobacco worm (Protoparce cecus and P. carolina).—Of these two insects the latter is said to be far more abundant than the former in Florida. The eggs are usually laid on the under surface of the leaves and hatch in about 3 days. The larva requires 3 weeks to attain its full growth. A description is given of the various stages of the insect.

As to treatment the author recommends hand picking, and gives a long account of the use of Paris green in controlling this insect. With regard to the danger from the use of Paris green on tobacco he says: "It will probably be on the side of caution to use weak mixtures of Paris green, as 1 lb. to 160 gal. of water. If this is applied properly and at the right time, when the worms are young, it will be sufficiently strong to kill them." If properly used, there should be no bad result from the use of Paris green on tobacco. Arsenate of lead is also recommended to be used in the form of a powder to be applied by an ordinary powder gun. Another remedy mentioned, which is said to be very effective, consists in pouring a small quantity of a poisonous mixture containing molasses into the flowers of the jimson weed, which are much frequented by these insects. The adult insects will thus be destroyed.

Among the natural enemies of the tobacco worm the author mentions a tachina fly (*Sturmia* sp.), *Apanteles congregatus*, and a brown wasp (*Polistes bellicosus*).

The suck fly (Dicyphus minimus).—This insect, which was first noticed in Florida in the year 1898, is said to be perhaps the most injurious insect to tobacco in the State. The suck fly damages the tobacco by sucking the juices from the leaves. The eggs are deposited in the tissue of the leaves and hatch in about 4 days. A description is given of the nymph and adult stages of the insect. The best remedy, in the author's opinion, is a strong decoction of tobacco. Whale-oil soap was tried, without good results. Kerosene emulsion and pyrethrum were found to be rather effective.

Cigarette beetle (Lasioderma sericorne).—This insect is recorded as being a very serious pest of stored tobacco in Florida and is said to attack other materials, such as pepper, ginger, rhubarb, and upholstery,

as well as dried plants. The best remedy is said to be bisulphid of carbon in closed boxes. A brief description of the different stages of the insect is given.

The tobacco-leaf miner (Gelechia picipetis).—The larva of this moth injures tobacco leaves by mining or eating out patches of the leaf substance, thus rendering the leaves unfit for wrappers. The life cycle of the insect is said to require not longer than 20 days, which makes it possible that several broods should occur in one season. The insect may be kept in check by spraying with Paris green in the manner recommended for the tobacco worms.

Cutworms.—Under this head brief notes are given on the cutworms in the State, with special reference to the species *Agrotis ypsilon*. The treatment recommended for cutworms is the use of bran poisoned with Paris green, in which the Paris green is used at the rate of 1 lb. to every 50 to 75 lbs. of bran.

Grasshoppers or locusts.—Two species of grasshoppers are said to be injurious to tobacco, *Pezzotettix femur-rubrum* and *P. birittatus*. Paris green is recommended for controlling these insects.

Bud worms (Heliothis sp.).—The common bollworm of cotton (*H. armigera*) causes considerable damage to tobacco. The eggs are deposited in the buds and the larva when hatched feed upon the young unfolding leaves. The remedy which has been found to be effective is the sprinkling of poisoned cornmeal into the bud of the tobacco plant.

The chinch bug, F. M. WEBSTER (*U. S. Dept. Agr., Division of Entomology Bul. 15, n. ser., pp. 82, figs. 19*).—The chinch bug is recorded as being distributed from St. Vincent and Granada, West Indies, into Lower California, on the west coast, to Cape Breton, on the east. It covers pretty largely the whole eastern portion of the United States as far west as Colorado and New Mexico. West of this line it is found only in isolated areas in California. The author maintains that the evidence which he has collected shows that the chinch bug hibernates only in the adult stage. Pupæ and undeveloped larval forms are found in late fall, but there is no evidence that these pass the winter. A favorite place of hibernation of the chinch bug is said to be in stools of the various grasses. Along the Atlantic coast chinch bugs may be found in the spring in great numbers in the stools of several maritime grasses, and in the interior the insects hibernate preferably in the matted blue grass, stools of timothy, and even under sticks and rubbish. Ordinarily about three migrations of the chinch bug may be observed annually—one in May, when the adults which have wintered over move away to new feeding grounds, one in midsummer, and one in the fall, during the so called Indian summer. These latter two hibernations, however, are said to depend upon the food supply, and if the food is abundant they are not observed to take place.

The eggs of the insect are said to be deposited "either about or below the surface of the ground, among the roots of the grass or grain." Ordinarily the female deposits about 500 eggs during a period

of from 10 days to 3 weeks. The author gives technical descriptions of the various immature stages, as well as of the adult.

With regard to the young bugs it is recorded that they are found mostly upon the lower portion of the plants which they attack. They are frequently found congregated in the sheaths of grasses, and often escape observation under those circumstances.

The number of annual generations for the greater part of the United States is two, but in Ohio the author thinks there is only one brood per year.

Attention is called to the fact that the chinch bug is always of a gregarious habit, and the suggestion is made that this indicates an original habit of living in tufts of grass from which the colony migrated.

Among the food plants are mentioned various maritime grasses, broom corn, sorghum, Bermuda grass, blue grass, wheat, rye, barley, corn, and timothy. The author has never witnessed serious attacks upon oats. A list of the various estimates of losses from the chinch bugs is compiled and explained in some detail.

Among the natural checks to multiplication of the chinch bug, meteorological conditions are considered the most potent factors. The adult insects, however, withstand heavy rains and the severe cold weather of winter; but the young, during the early stages, are easily destroyed by wet weather, particularly by severe windstorms. Consequently, devastations caused by the chinch bug in any particular year will depend very much upon the number and character of the rain storms which occur during the time of the early development of the young chinch bugs. During the latter stages of the immature bugs, heavy rain storms are of little avail.

The two best-known parasitic fungi which attack the chinch bug, *Entomophthora aphidis* and *Sporotrichum globuliferum*, are described. It is a well-known fact that both of these fungi cause more destruction to the chinch bug during a wet season than during an exceedingly dry one. Another rather doubtful enemy of the chinch bug is *Bacillus insectorum*. This bacterium also vegetates more luxuriantly during moist weather.

Various experiments in scattering diseased chinch bugs and cultures of the two fungus parasites of the chinch bug are described, and the results of these experiments, which the author made in Ohio, are recorded as very encouraging.

Among the bird enemies of the chinch bug, the quail is said to be the most important. The other bird enemies which are mentioned are the prairie chicken, red-winged blackbird, catbird, brown thrush, meadow lark, and house wren.

“Perhaps the worst insect enemies of the chinch bug are to be found among its comparatively near relatives, the insidious flower bug, *Triphleps insidiosus* Say (*Anthocoris pseudo-chinche* of Fitch's Second Report), and *Milyas cinctus* Fab., the latter being reported by Dr. Thomas as the most efficient of the insect enemies of this pest, while

Dr. Riley found that the former also attacked it. Professor Forbes ascertained by examinations of the contents of the stomach of a ground beetle, *Agonoderus pallipes* Fab., that one-fifth of the total food of this species was composed of chinch bugs. Drs. Shimer and Walsh both claim that lacewing flies (*Chrysopa*) destroy chinch bugs, and they are doubtless correct."

Among the artificial remedies, the author suggests the burning over of old grass lands and the burning of all rubbish under which the chinch bug might hibernate. Another remedy suggested is that of sowing protective grasses, as decoy crops for the chinch bug, and thoroughly plowing these under when they become infested by the migration of the chinch bug. The well-known coal-tar method was tried and found to be very successful. The author also tried the method of plowing deep furrows and digging post holes at intervals along the inner line of these furrows, into which the chinch bugs fall and are later destroyed. The use of kerosene emulsion as a spray to be applied directly upon the infested crops gave good results and proved itself very effective in destroying the chinch bug, even when used in a weak solution.

The summary of the author's remedial measures is as follows:

"The insects may be destroyed in their places of hibernation by the use of fire. They can, under favorable meteorological conditions, be destroyed in the fields, if present in sufficient abundance during the breeding season, by the use of the fungus *Sporotrichum globuliferum*, if promptly and carefully applied. They can be destroyed while in the act of migrating from one field to another, by tarred barriers or deep furrows supplemented by post holes, and by being buried under the surface of the ground with the plow and harrow; or the latter method can be applied after the bugs have been massed upon plats of some kind of vegetation for which the bugs are known to have a special fondness, which decoys should be so arranged as to either attract the females and induce them to oviposit therein, or they should be arranged with the idea of intercepting an invasion from wheatfields into cornfields, and, by turning these decoys under with a plow and immediately smoothing and packing the surface by harrow and roller, thus destroying them. While in the cornfields they can be destroyed on the plants by applications of kerosene emulsion."

The author believes, from all evidence at hand, that the original home of the chinch bug was in South or Central America, and that the United States has been infested from its original home. He gives a map showing the supposed course of migration of the chinch bug from Central America up the Pacific coast of this country, along the Gulf States, up the Atlantic coast, and directly north through the Mississippi States.

The periodical cicada, C. L. MARLATT (*U. S. Dept. Agr., Division of Entomology Bul. No. 14, n. ser., pp. 148*).—The general habits and peculiarities of the insect are mentioned in the introduction to the bulletin. The author distinguishes between the 17-year and 13-year broods, and gives an account of the arguments for and against the idea of these two forms being distinct species. All forms, including the dwarf form, are considered as belonging to one species.

The author believes that there was originally but one brood in the United States, but that in consequence of slowly changing geological

and climatic conditions several broods of both the 17-year and 13-year forms have been definitely differentiated in time of appearance and in locality. The validity of 21 broods has been established. Of this number 14 belong to the 17-year race and 7 to the 13-year race. The periodical cicada is shown to be pretty generally distributed over the country east of the Rocky Mountains. A detailed account is given of the exact distribution of each brood and of the years when it has been known to appear, and from these data predictions are made as to future appearances of the different broods. In general the 13-year race is shown to be southern and the 17-year race northern, but no arbitrary boundary line can be established, for small broods of both races extend over the dividing line.

A long and careful account is given of the systematic position and anatomical structure of the cicada. Its musical apparatus and song are described, and the popular tales concerning the so-called sting of the insect are considered. The author gives an elaborate account of the occurrence, nature, and purpose of the cicada cones, of the transformation and emergence of the adult, and of the length of life of the adult. In his account of the habits of the adult insect he says: "They often also appear in greatest number in rather well defined districts within the general range of the brood, or, in other words, are irregular in local distribution. This variation in abundance is due in some cases to differences in the character of the soil, and in other perhaps to varying surface conditions, as of timber growth, etc."

The feeding habits of the adult cicada are described and an account is given of various attempts to use the cicada for food. The author names the plants upon which the insect deposits its eggs, and says that a preference is shown for oak, hickory, and apple. The process of oviposition is described in great detail. "The female," says the author, "deposits the row of eggs on one side as she makes the original cutting in the bark. She then moves back, and, swinging a little to one side, inserts through the same hole the second row of eggs parallel with the first, thus leaving a small bit of undisturbed wood fiber between the two rows of eggs."

The normal period of incubation for the eggs is said to be from 6 to 7 weeks. As soon as the larva becomes free it "begins to run actively about with the quick motions of an ant, but soon goes to the side of the limb, loosens its hold, and deliberately falls to the ground."

The experimental and other proofs of the length of the underground larval and pupal life are enumerated and discussed. Four larval stages and two pupal stages are distinguished and described. The root-feeding habit of the larva is described in some detail. The larvae are said to occur in greatest number at a depth of from 8 to 18 in. in the soil. The damage caused during the underground life of the insect is considered very slight.

Among the natural enemies of the cicada are mentioned reptiles, quadrupeds, birds, ground beetles, dragon flies, soldier bugs, hogs, and

poultry. Among birds the English sparrow is said to be especially destructive to the cicada. The following insect parasites of the cicada are recorded: A Cecidomyid egg parasite and a number of Hymenopterous egg parasites, and several mites of the genera *Oribatella*, *Oripoda*, *Oppia*, *Pediculoides*, *Tyroglyphus*, *Iphis*, *Cheyletus*, and *Bdella*. A few predaceous Hemiptera and the digger wasp (*Megastizus speciosus*) are mentioned as important enemies of the cicada.

As artificial remedies the author recommends the use of nets on small trees to prevent the insects from depositing their eggs. Pyrethrum, applied either as a powder or in water and kerosene emulsion, was found to be an effective remedy when sprayed upon the adult cicada. For destroying the cicada during its underground life, tobacco dust in the soil and bisulphid of carbon are recommended. The author reviews the more important papers on the cicada and gives an extensive bibliography of the subject.

The grapevine flea-beetle, M. V. SLINGERLAND (*New York Cornell Sta. Bul. 157, pp. 189-213, figs. 19*).—The author gives a review of the literature of the subject and a description of the insect in its various stages. Among the food plants of this flea-beetle are mentioned the wild and cultivated grapes, plum trees, the water beech, apple, and quince. No decided preference is shown by the insect for any special variety of grape. The greatest damage is done by the adult beetle in early spring in eating the undeveloped buds and thus preventing the formation of fruit. The adult beetles work upon the young buds only a few days, but when they occur in large numbers this time is usually sufficient to cause great destruction. The eggs are laid from the middle of May to the middle of June. The time of incubation was not determined. It is supposed to be about 3 weeks. The young grubs feed upon the leaves and are usually found upon the upper surface. The pupal stage is passed about an inch or two under the surface of the soil and lasts about a week. The adult beetles then attack the leaves late in the summer in about the same way that the grubs do during the earlier part of the season. The evidence seems to show that there is but one brood of the insect in New York. The insect passes the winter in the adult stage, hiding in grass and under rubbish and in the cracks of bark, and emerges from the hiding places in April and May.

Among its natural enemies are recorded *Podisus modestus* and *Megilla maculata*. Much good may be done by removing and burning all bark, splinters, and rubbish in the vicinity of the vines in the fall, thus destroying the hibernating beetles. In the early spring, when the beetles first emerge, they may be readily jarred into a pan of kerosene or upon sheets saturated with kerosene. The most effective remedy, however, is spraying with Paris green, at the rate of 1 lb. of Paris green to 150 gal. of water for the purpose of destroying the grubs. The grubs may be readily seen as they feed upon the upper surface of the leaves. Paris green may be used as a spray against the adult beetles before the development of the buds, and may then be used in

the proportion of 1 lb. to 75 gal. of water with the addition of a pound of lime.

An extensive bibliography is appended to the bulletin.

The Hessian fly in the United States, H. OSBORN (*U. S. Dept. Agr., Division of Entomology Bul. 16, n. ser., pp. 57, pls. 2, figs. 8, map 1*).—The original home of the Hessian fly is left in doubt, with the suggestion that it probably was the same as that of wheat. The distribution of the insect is practically coextensive with the wheat-producing regions of Europe and America. The author mentions two means of distribution of the Hessian fly; the first and less important is the slight power of flight, while the chief means is transportation in straw containing puparia or flaxseeds. "The introduction into the United States near New York City has as its most probable foundation the straw used as bedding by the Hessian troops landed during 1776 and 1777, and while there is lacking positive evidence that the insect existed at the point of their starting or even of embarkation, the source of straw they might have used and scattered after landing may have been in some infested locality." A careful description is given of the entomological details and of the life history of the insect, including the 3 larval forms and the pupal.

As to the question of the number of broods per year, the author believes that in the northern and eastern part of the country the insect passes through 2 broods per year, but that temperature and moisture conditions have a great influence in retarding or accelerating development. "The Hessian fly presents variations not only in the number of broods, from 1 to possibly 5 or 6, depending upon latitude, but by acceleration or retardation, under conditions peculiar to each year, it may appear earlier or later and in a greater or less number of broods in the same locality. This variation naturally enhances the difficulty of stating life history details with precision and making recommendations as to particular dates on which to adopt measures of control." Certain authorities have recorded the Hessian fly as having been found upon a number of cultivated grasses. The author, however, does not accord accuracy to these observations, but states that "in any deductions relating to the control of the Hessian fly, it may be considered for all practical purposes that the insect lives only on wheat, rye, or barley, and will not perpetuate itself on other plants." An account is given of the different effects on the host plants depending upon whether the attack is made in the spring or fall.

Under the head of the natural enemies of the Hessian fly the author lists a number of primary and secondary parasites as found in this country, and gives a list of parasites as recorded in Russia, England, and France. The primary parasites found in this country are described and figured, and an account is given of their biological relationship. The author gives a history of the introduction by Dr. Riley of the parasite *Entedon epigonus* from Russia, and of the success of its introduction.

Among other natural enemies of the Hessian fly are mentioned nematode worms and thrips.

As to artificial remedies, the author recommends the burning of stubble as soon after the cutting of the grain as possible in case of a moist season. This remedy is not so necessary during a dry season. In certain cases it may be advisable to plow under the stubble. In order that this may be effective the ground should be plowed to a depth of several inches. It is also recommended that all volunteer wheat be destroyed in order that belated individuals may not find a food supply. The author further recommends a rotation of crops such that wheat shall not come 2 years in succession on the same ground, and also that fall wheat should preferably be sowed late rather than at the beginning of the fall season in order to avoid attacks of the Hessian fly upon the young developing wheat. Such remedies as pasturing fall wheat with sheep, rolling the wheat with a heavy roller in the fall, and mowing the young wheat are considered by the author as being of but little avail. It is stated that certain varieties of wheat have been found to be more resistant to the attacks of the Hessian fly than others, and a selection of varieties may be made accordingly.

Of the various insecticides which have been used, none have ever been effectual and none are therefore to be recommended.

A rather complete bibliography of the literature on the Hessian fly is appended to the bulletin, containing 141 titles.

The use of hydrocyanic-acid gas for fumigating greenhouses and cold frames, A. F. WOODS and P. H. DORSETT (*U. S. Dept. Agr., Division of Entomology Circ. 37, 2. ser., pp. 10, figs. 3*).—Greenhouse plants were less injured by a short exposure to a large amount of gas than by a long exposure to a small amount of the gas, and at the same time the insects were more thoroughly destroyed by the large amount of gas for a short time. It was found that fumigation after sundown with the temperature as low as practicable gave the best results. For ferns 0.075 gm. of 98 per cent cyanid of potash was used for each cubic foot to be fumigated. The ferns were infested with *Chionaspis*. All the insects were destroyed. Coleus and other related plants were fumigated at the rate of 0.1 gm. of 98 per cent cyanid of potash per cubic foot of space. Double English violets were fumigated at the rate of 0.15 gm. of 98 per cent cyanid of potash for each cubic foot of space. Roses were found to be especially sensitive and many of them were more or less injured in all of the experiments. Carnations were found to endure 0.1 gm. of cyanid of potash per cubic foot for 15 minutes. Grapes under glass endured 0.09 gm. per cubic foot. Tomatoes withstood 1 oz. of pure cyanid of potash for each 1,000 cu. ft. Careful directions are given for obtaining the cubic space of greenhouses and for calculating the necessary amount of cyanid to be used in each case.

The materials to be used are 98 per cent cyanid of potash and commercial sulphuric acid. Earthen jars 1½ or 2 gal. in capacity and of

small diameter are recommended as vessels in which to produce the gas. There should be 1 jar for each 50 ft. in length of an ordinary greenhouse. The cyanid of potash is weighed out and inclosed in paper bags, which may be suspended by a string directly over the jars and can be lowered from the outside of the greenhouse. An amount of water should be poured into each jar equal to the amount of potassium cyanid in the bag, or about $\frac{1}{2}$ pt. of water to each 8 oz. of cyanid. Sulphuric acid should then be added until the water steams. The house should be tightly closed. The bags are then lowered into the jars for the necessary length of time. The greenhouse should be ventilated for at least half an hour before entering.

Report to the Royal Ministry of Agriculture concerning work of the State entomological department for the year 1898, S. LAMPA (*Ent. Tidskr.*, 20 (1899), No. 1, pp. 70).—Contains notes on a large number of economic insects and their injuries in Sweden, including *Argyresthia conjugella*, *Cecidomyia destructor*, and *C. tritici*.

Insects collected on Mount Fugi, M. MATSUMURA (*Annotationes Zool. Japonenses*, 2 (1898), pt. 4, pp. 113-124).—Gives a considerable list of insects which are noted as occurring in zones at different elevations on the mountain.

Acclimatization of beneficial insects (*Rov. Lapok. G* (1899), No. 4, pp. 88).—*Fedalia cardinalis* from California has been successfully introduced into the Sandwich Islands.

A serviceable insectary, F. M. WEBSTER (*Canad. Ent.*, 31 (1899), No. 4, pp. 73-76).—Describes the insectary used in the Ohio Station.

The common blue tick of Cape Colony and its relationship to the red water ticks of North America and Australia, C. FULLER (*Agr. Jour. Cape Good Hope*, 14 (1899), No. 6, pp. 363-369).—Contains an analytical table of the species of Rhipicephalus. The American *Boophilus boris* is called *B. annulatus* and the local blue tick of the colony is called *B. decoloratus*. The latter, like the American species, carries red water from animal to animal.

Codling moth, C. P. LOUNSBURY (*Agr. Jour. Cape Good Hope*, 14 (1899), No. 5, pp. 287-287).—Reminds fruit growers of the dangers from this insect in the colony.

A new rival of the codling moth, E. REUTER (*Ent. Tidskr.*, 20 (1899), No. 1, pp. 71-76).—*Argyresthia conjugella* is described, with an account of its life history and distribution and its injuries to the apple.

Phylloxera, L. DE SISTERNES (*Bol. Agr. Min. Ind., Mexico*, 8 (1898), No. 4, pp. 11-39).—The article contains an account of the life history, habits, and injuries resulting from the phylloxera, together with a description of the insect in its various stages. As remedies the author suggests pulling out the weak vines, flooding the vineyard, the use of insecticides, destruction of winter eggs, rearing its insect enemies, planting in sandy soil, and the use of American varieties.

Some notes on the grape-cane gall maker (Ampelogypter sesostris), F. M. WEBSTER (*Ent. News*, 10 (1899), No. 3, pp. 53-55, pl. 1).—Notes on the habits of this insect in Gypsum, Ohio. Two parasites reared *Catolaccus tyloderma* and *Myiophasia aenea*.

Pieris brassicæ (*Jour. Bd. Agr. [London]*, 5 (1899), No. 4, pp. 459-463).—Gives the life history and remedies for controlling this insect.

The cottony cushion scale, H. A. GOSSARD (*West Hillsboro Press*, 5 (1899), No. 37).—A popular article.

Seasonal dimorphism in Lepidoptera, ROLAND TRIMEN (*Nature*, 59 (1899), No. 1537, pp. 568-573).—The author considers this phenomenon in a large number of species, and suggests the establishment of zoological stations for studying the subject.

Investigations on the accelerated development of hibernating butterfly pupæ, H. GUCKLER (*Illus. Ztschr. Ent.*, 4 (1899), No. 7, pp. 103-105, pl. 1).—Relates experi-

ments which show the effect of increased temperature in hastening the development of butterfly chrysalids.

Operations with a locust fungus (*Agr. Jour. Cape Good Hope, 11 (1896), No. 5, pp. 296-296*).—Reports the apparently successful use of pure cultures of a fungus for the destruction of locusts. Although not here stated, the fungus is probably *Empusa grillo*.

FOODS—ANIMAL PRODUCTION.

The constituents of the seed of *Pinus cembra*, E. SCHULZE and N. RONGGER (*Landw. Vers. Stat., 51 (1898), No. 2-3, pp. 189-201*).—The authors made an extended microscopical and chemical study of the seeds of *Pinus cembra*. These seeds are edible and are known as "Zirbel" nuts or "Arve." Analyses of the seeds include the study of the whole seed, the shell, and kernel. Owing to the large amount of fat present, it was found necessary to extract a considerable portion of the fat before the final grinding for analysis.

The shell constitutes 62.6 per cent and the kernel 37.4 per cent of the total dry matter of the seeds. The dry matter of the shell had the following percentage composition: Protein 0.84, fat 1.18, nitrogen-free extract and crude fiber 98.18, ash 0.80. The dry matter of the kernel had the following composition: Protein 17.24, glycerids of free fatty acids 49.26, lecithin 0.99, starch 7.43, water soluble nitrogen-free substances 16.84, crude fiber 1.19, ash 3.5.

The authors state that the ash is said to contain much phosphoric acid, and is undoubtedly rich in alkali. More than 80 per cent of the total ash was found in an aqueous extract of the seeds.

Vinegar adulteration and the extent to which it exists in the samples for sale in North Carolina, W. A. WITHERS and J. A. BIZZELL (*North Carolina Sta. Bul. 153, pp. 25-32*).—Twenty samples of vinegar sold in the State were examined. Thirteen compared favorably with cider vinegar as far as the amount of acetic acid was concerned and 5 were too weak in acid. The amounts of total solids and ash indicate that only one sample was pure cider vinegar. One of the samples was sold as grape vinegar; 2 samples were apparently diluted with water; 17 appeared to be spirit vinegar, with the addition of organic coloring matter. The so-called grape vinegar was spirit vinegar with coloring matter. Ninety-five per cent of the samples analyzed were adulterated. The authors recommend "(1) that all vinegars shall contain not less than 4 per cent by weight of absolute acetic acid, and must contain no lead, copper, mineral acids, or artificial coloring matter; (2) that all vinegars must be branded with the name of the fruit or substance from which they are made, together with the name and address of the manufacturer; (3) cider vinegar shall not contain less than 1 $\frac{3}{4}$ per cent by weight of cider-vinegar solids."

The North Carolina act to prevent the sale of adulterated or misbranded foods is quoted.

Concentrated feed stuffs, J. B. LINDSEY ET AL. (*Massachusetts Hatch Sta. Bul. 56, pp. 21*).—The authors report the examination of concentrated feeding stuffs in accordance with the law in Massachusetts.

The feeding stuffs examined were cotton-seed meal, linseed meal, gluten meals, gluten feed, wheat bran, wheat middlings, Red dog, mixed feeds, miscellaneous concentrated feeds, corn meal, oat feeds, corn and oat feeds, corn, oat, and barley feeds, hominy feeds, miscellaneous starchy feeding stuffs, and poultry foods. Among the suggestions drawn from the examination were the following:

"Farmers are especially cautioned against adulterated cotton-seed meal. Samples of this substance were found in a large number of towns, especially in northeastern Massachusetts, during the spring months. Sea-island cotton seed, so called, is also very much inferior to the genuine material. . . . It is . . . only one-half as valuable as the prime article. It is evidently prepared by grinding the black hulls quite fine and mixing them with the yellow meal. The resulting product is as a rule of a darker yellow than the pure meal. Samples of adulterated meal have also been found that were bright yellow. This meal had either been artificially colored or mixed with some inferior substance other than hulls. We urge purchasers to buy only the guaranteed article, and to absolutely refuse the unbranded meal. Pure cotton-seed meal is one of the very cheapest concentrated feed stuffs. Linseed meals, branded gluten meals, and gluten feeds examined show no adulterations. Wheat bran, middlings, and, with a few exceptions, mixed feeds, have not been found to contain any foreign admixtures. Heilman's mixed feed was found to be of very poor quality. It contained a large amount of woody material, of very little feeding value. Several unmarked mixed feeds were similarly adulterated. The Lexington mixed feed showed several per cent less protein than the average. Many unbranded oat feeds have been found to contain as high as 65 per cent of hulls and only from 5 to 7 per cent of protein. Such foods prove costly at prices asked for them. See more extended remarks under analyses of these feeds."

Dried grains as a substitute for hay, J. A. VOELCKER (*Jour. Roy. Agr. Soc. England, 3. ser., 9 (1898), pt. 4, pp. 768-774*).—A test was made with steers at the Woburn Farm to learn how far dried brewers' grains could advantageously replace hay in a time of scarcity. Sixteen Shorthorn 3-year-old steers were divided into 2 lots of 8 each. Four animals of each lot were fed in stalls, 2 in sheds, and 2 in open yards. The test began December 22, 1897, and was divided into two periods of 40 and 70 days, respectively. During the first period lot 1 was fed dried brewers' grains *ad libitum*, and lot 2 cut hay *ad libitum*. In addition each lot at the beginning of the test was fed 3 lbs. decorticated cotton-seed cake, 3 lbs. of maize meal, and 28 lbs. of Swedish turnips. After about 6 weeks the grains were each increased to 4 lbs. and the Swedish turnips to 35 lbs. After a time mangel-wurzels were substituted for Swedish turnips, and in the latter half of the period linseed cake was added to the ration. During the test lot 1 consumed 4,178 lbs. dried brewers' grains and the average daily gain per steer was 2.18 lbs. Lot 2 consumed 5,820 lbs. of hay, the average daily gain per steer being 3.05 lbs. The cost of the gain is discussed and it appeared that the more economical gains were made with hay. From this test, "as also from general observations throughout the experimental period, it was shown that in steer feeding it does not do to replace hay entirely by dried grains." The test was continued with the same steers to see whether dried brewers' grains might not to advantage replace hay in part. The steers in lot 1 were fed 5 lbs.

of hay chaff daily and as much dried brewers' grains as they would eat, in addition to the same ration as before. It was found that this method of feeding did not materially diminish the amount of dried brewers' grains consumed. Lot 2 was fed the same ration as during the first period. As the test continued it was observed that with lot 1 there was a tendency to consume less coarse fodder, but this was also observed with the lot fed hay. In the 71 days of the second period the steers in lot 1 made an average daily gain of 2.60 lbs., those in lot 2, 2.20 lbs. The gain is discussed at some length from a financial standpoint.

"It would appear that while dried grains, used along with a small quantity of hay chaff, can replace hay quite well as a food for bullocks and give a larger increase of live weight, yet at the respective prices quoted for dried grains and hay [\$21.50 and \$15.83 per long ton (2,240 lbs.), respectively, including transportation and cutting or chafing] and carcass meat [7 cts. per pound], there is very little monetary difference whether dried grains are used along with the small quantity of hay chaff, or whether hay chaff is used alone. Further, from the earlier part of the experiment it is clear that dried grains can not be made to replace hay entirely for bullock feeding, but that hay or similar food must be used along with them. Also that the same weight of fibrous food will be required whether hay be used alone or as a supplement to dried grains."

The maintenance ration of cattle, H. P. ARMSBY (*Pennsylvania Sta. Bul. 42, pp. 188, pls. 18*).—The author reports a series of experiments with steers, extending from 1892 to 1897, to learn the amount of food required for maintenance. In all cases the feeding was continued for long periods. During a portion of the period the digestibility of the ration was determined as well as the balance of income and outgo of nitrogen. Records were kept of the gains or losses in live weight and in many cases of the amount of water consumed, and of variations of the temperature of the stalls in which the steers were kept. In some of the tests the results were calculated in overlapping 10-day periods, since the author believed that it was thus possible to eliminate errors. In the several experiments the gain or loss of protein and fat was estimated as well as the fuel value of the ingesta and egesta (in the later experiment fuel values were determined), due allowance being made for the estimated energy of the urine and the methane. In all the tests 3 steers were used. They were apparently grade Shorthorns and in 1892 were past two years old. They weighed at the beginning of the experiments 427.7 kg., 457.9 kg., and 407.3 kg., respectively.

The first experiment began December 1, 1892, and covered 52 days. Previous to the test the steers had been fed nothing but hay. During the test the ration consisted of 4.563 kg. of timothy hay containing a little clover. From January 15 to 21 the digestibility of the ration and the income and outgo of nitrogen was determined.

The second test began January 22, 1898, and covered 71 days. The ration in the first test having proved insufficient, the amount of timothy hay was increased to 5.44 kg. The special digestion and metabolism experiment began February 19 and covered 7 days.

The third experiment began November 16, 1893, and covered 51 days. In this experiment the ration consisted of timothy hay and corn meal,

the amount fed at the beginning being 5.444 kg. of hay and 0.455 kg. of corn meal. The amount of hay was gradually decreased and the corn meal increased to November 21 until the amounts fed were 2.948 kg. of timothy hay and 1.474 kg. of corn meal, this ration being continued throughout the experiment except in the case of a few days when steer No. 3 was ill and received different food. The special digestion and metabolism experiment began December 16 and covered 7 days.

The fourth experiment began January 6, 1894, and covered 70 days. In this test new-process linseed meal was gradually substituted for corn meal until 1.678 kg. was fed. The amount of hay was the same as in previous test. Steer No. 3 showed a tendency to decrease in weight, and his ration was therefore increased to 3.629 kg. of hay and 1.814 kg. of linseed meal. The special digestion metabolism experiment began February 21 and covered 7 days.

The fifth experiment began March 17, 1894, and closed April 21. The primary object of this test was to learn the digestibility of the so-called "cotton-seed feed," which it was claimed consisted of cotton-seed meal and hulls 1:5. The special digestion and metabolism experiment began April 15 and ended April 21. This test has been reported in a previous publication (E. S. R., 6, p. 1014).

The sixth experiment was made in 1894-95. The steers had been in pasture during the spring and early summer. The latter part of July they were put on a ration of 5.44 kg. of timothy hay. August 17 this was replaced by the same quantity of long hay, consisting chiefly of timothy with some admixture of blue grass. After a few days this was replaced by the same amount of cut hay such as was used during the experiment proper. From July 22 until the beginning of the experiment proper the weight of the steers and the amount of water consumed was recorded. The experiment proper began November 28 and extended over 106 days. At the beginning of the experiment the daily ration consisted of 6.35 kg. of mixed clover and timothy hay. After December 13 this was replaced by the same amount of cut timothy hay. In this test the steers were kept in special stalls, which are described in detail. They were essentially the same as the so-called Bidwell stall. The digestibility of dry matter and nitrogen was determined throughout the whole experimental period, with the exception of the interval from February 15 to March 6. The special digestion experiment began January 12 and closed January 18. The nitrogen in the urine was determined throughout the whole test.

The seventh experiment, which covered 41 days, began March 14, 1895. Starch was gradually substituted for a part of the hay until the ration consisted of 5.2 kg. of hay and 0.8 kg. of starch. From March 28 until the close of the test the digestibility of the dry matter and nitrogen was determined as well as the nitrogen in the urine. The special digestion period covered 7 days, beginning April 13.

The eighth experiment began December 27, 1896, and covered 96 days. Wheat, straw, corn meal, and linseed meal were gradually substituted for the previous ration until on January 15, steer No. 1 was fed 2 kg. of wheat straw, 2.5 kg. of corn meal, and 0.5 kg. of linseed meal. Steers Nos. 2 and 3 were fed the same amounts of wheat straw and linseed meal and 2.75 kg. of corn meal. These rations were continued throughout the test. The digestibility of the ration was determined from January 29 to February 11, and from March 12 to 28.

All of these tests are discussed in detail. The digestibility of the different rations and the balance of income and outgo of nitrogen are shown in the following table:

Coefficients of digestibility and income and outgo of nitrogen in experiments with steers.

a Excluding experiments 3 and 4.

As previously stated, rations were selected which it was believed were just sufficient for maintenance, their value for this purpose being judged by variations in live weight and gain or loss of nitrogen. The author compares his results with those of other investigators, and concludes that the average steer weighing 500 kg. when fed a ration consisting only or mainly of coarse fodder requires for maintenance 13,000 calories of available energy at a stable temperature of 50 to 60° F. after making a deduction for the loss of energy in the form of methan. The amount of protein required is also discussed.

“It would appear that with a nutritive ratio of about 1:11, a minimum of about 300 gm. of proteids per day and 500 kg. live weight is required for maintenance, and that any material diminution of this amount will result in a loss from the body. Furthermore, however, it would appear that if the nutritive ratio be made wider, this amount of proteids may be very materially reduced, at least for a time, without leading to a loss of nitrogen by the body or to any recognizable injurious consequences.

“Finally, it may not be superfluous to point out that the term proteids as here employed, following the common usages, is a conventional term. Neither the variations in the percentage of nitrogen in the vegetable proteids nor the presence of nitrogenous metabolic products in the feces has been taken account of. As regards the former, our knowledge of the composition of the proteids of coarse fodders is insufficient to enable us to substitute any other factor for the conventional 6.25, so that only in one experiment (No. 8) was there any approximately sufficient basis for recalculation of the analytical results.

“The metabolic products in the feces can be determined with some degree of accuracy, but inasmuch as they are waste products it makes little practical difference in any single experiment of this sort whether we correct the apparent digestibility of the proteids for them in order to obtain the true percentage digestibility and say that the ration contained, e. g., 325 gm. of digestible proteids, of which 25 gm. was required to make good the excretion of metabolic products in the feces, or whether we subtract the total proteids of the feces from those of the food and say that the ration contained the net amount of 300 gm. of proteids available to the body.

“In the case of widely different rations, of course, the proportion of metabolic products may vary and thus distort the comparison, and undoubtedly their determination is desirable, but it is not believed that the failure to take account of them in these experiments seriously affects the value of the results as regards proteids, while, as already pointed out, the results of the energy of the rations are independent of it.”

The relative value of coarse fodder and grain is also spoken of at length. The article contains an extended review of the literature of the subject, and the author's results are compared with those of other investigators.

Experiments on the value of meadow hay, W. VON KNIERIEM (*Landw. Jahrb.*, 27 (1898), No. 3-4, pp. 521-565).—Investigations conducted at the Peterhof Experimental Farm are reported. These investigations extended over several years and represent the work of a number of individuals. Experiments with rabbits are reported on the digestibility of white and red clover, kidney vetch, spring vetch, timothy, perennial rye grass, orchard grass, and water avens, and with sheep and cows on the digestibility of mixed grasses, clover, and sour grass.

The relation of the different parts of orchard grass and timothy of luxuriant growth and stunted growth was studied. Measurements of the growth of yellow rocket (*Barbarea vulgaris*) and studies of the composition, including fertilizer constituents, of the stem and leaf were also made.

In addition to digestion experiments with cows the comparative value of clover hay and sour grass hay for the production of milk was studied. Feeding sour grass hay diminished the milk yield, while clover hay increased it.

The relative digestibility of foods by different animals is discussed. The majority of feeding stuffs are said to be about equally well digested by different ruminants. When, however, the feeding stuff contains a small amount of nutritive material it is better utilized by cows than by sheep. The results obtained with rabbits are believed to be comparable with those obtained with the larger animals.

Investigations on the value of different concentrated feeding stuffs, W. VON KNIERIEM (*Landw. Jahrb.*, 27 (1898), No. 3-4, pp. 566-630).—These experiments, which extend over a number of years, were conducted by different investigators at the Peterhof Experimental Farm. Experiments are reported with rabbits, sheep, and horses on the digestibility of cocoanut cake, hemp-seed cake, linseed cake, sunflower-seed cake, rape-seed cake, meadow hay, and a number of mixed rations. In some cases the digestibility of the concentrated feeding stuff was calculated by deducting from the digestibility of the mixed ration the calculated digestibility of the other feeding stuffs, and in others it was determined by changing the ratio of the foods and calculating the digestibility algebraically on the basis of the differences observed. The results obtained by the two methods of calculation are compared.

In a number of the experiments the balance of income and outgo of nitrogen was also determined.

Tests of the effect of cocoanut cake and linseed cake on the yield and composition of milk were also reported with 2 cows. The cocoanut cake increased the milk yield 16 per cent, and the linseed cake 12 per cent. Notwithstanding the fact that the fat in the two sorts of cake possessed such different properties, the butter made when these cakes were fed was not materially changed as regards melting point, cooling point, or content of nonvolatile acids. As regards the volatile acids, so great irregularities were observed that no deductions could be drawn.

A test of the effect of palm-nut cake on the yield and composition of milk was also made. It was fed with clover hay. As compared with periods when clover hay was fed alone, palm-nut cake increased the production of milk about 17 per cent. The fat content of the milk was also increased. Butter made from milk obtained in the different periods was compared. The saponification number of the butter was increased when palm-nut cake was fed.

In this and the preceding article, a large number of investigations by other observers are cited, often in considerable detail.

The relative values of different fibrous foods for sheep, J. A. VOELCKER (*Jour. Roy. Agr. Soc. England*, 3. ser., 9 (1898), pt. 1, pp. 774-786).—A test was made at Woburn Farms to ascertain the most satisfactory coarse fodder for sheep in addition to roots. Sixty Hampshire Down lambs, showing a little Oxford blood, were divided into 4 lots of 15 each. Lot 1 was fed cut (or chaffed) oat straw, lot 2 cut meadow hay, lot 3 cut meadow hay and cut oat straw 1:1, and lot 4 dried brewers' grains. In addition the sheep were given Swedish turnips. These feeding stuffs were supplied *ad libitum*. All the lots were also given the same amount of linseed cake. The test began November 29, 1897. The financial statement is based on linseed cake at \$42.63, dried brewers' grains at \$21.50, oat straw at \$7.86, meadow hay at \$15.83, and Swedish turnips at \$1.75 per long ton (2,240 lbs.). These values include cutting or chaffing and transportation. March 7, 6 sheep from each pen were sold and slaughtered; March 28, 5 sheep from lots 1, 3, and 4, and 4 from lot 2 (one sheep in this lot had died) were sold and slaughtered. The remainder of the sheep were disposed of April 20. Considering the test as a whole, the average daily gain per head of lot 1 was 0.405 lb.; of lot 2, 0.425 lb.; of lot 3, 0.433 lb., and of lot 4, 0.409 lb. The percentage of live weight to carcass in the 4 lots was 51.84, 51.68, 52.49, and 52.56, respectively. The greatest profit was realized with lot 3. The tests are reported and discussed in detail:

"In making these comparisons it has to be borne in mind that the money values put upon the roots, the oat-straw chaff, and the hay chaff are only estimates, and these may well be reduced in particular cases, seeing that the foods are home-produced, whereas in the case of the dried grains the actual prices put down had to be paid.

"It was abundantly clear, however, that the sheep did exceedingly well on the dried grains and liked the food greatly; also that hay could be entirely replaced by dried grains, a result different from that obtained in a similar experiment on bullocks (see p. 1078). But it can not be said that the feeding with dried grains was more profitable than with hay chaff, while a mixture of hay chaff and oat-straw chaff, half and half, proved to be the most economical feeding.

"The question of the profitable employment of dried grains for fattening sheep must clearly depend upon whether the price of the grains greatly exceeds that of hay or not."

The influence of manures on the production of mutton, W. SOMERVILLE (*Jour. Bd. Agr. [London]*, 5 (1898), No. 3, pp. 300-314).—A test was made to compare different methods of fertilizing poor pasture land as shown by the gains made by sheep pastured on the different plats fertilized, the results being compared with the yield of hay on the different plats. The tests were begun in 1897 and covered 2 years. The fertilizers were applied in 1897 only. There were 10 plats of 3 acres each and in each plat a subplat of one-twentieth of an acre was fenced off. Sheep were pastured on the large plats and the hay on the subplats was harvested. The fertilizers were so regulated that 200 lbs. per acre of phosphoric acid was applied to plat 3; 100 lbs. per acre to

plats 4, 5, 7, 8, 9, and 10; 50 lbs. per acre of potash to plat 7; and 20 lbs. of nitrogen per acre to plat 9, and 17.2 lbs to plat 10. Plat 1 received no direct manuring; the sheep grazing on it, however, were fed $\frac{3}{4}$ lb. per head daily of decorticated cotton-seed cake. About 6 cwt. per acre of ground cotton-seed cake was applied to subplat 1. At the end of 3 years the pastured area of plat 1 will have received about the same amount of nitrogen in the form of manurial residue as was added in the form of crushed cake to the subplat. Plat 6 was not fertilized and served as a control.

Beginning June 27, 1897, 8 crossbred sheep were pastured for 16 weeks on each of the plats. In 1898 the sheep were turned into pasture May 16. Six sheep were placed on plat 6; 8 on plats 2, 4, 5, 7, 8, 9, and 10, and 10 on plats 1 and 3. Six weeks later 1 more sheep was added to plats 1 and 7 and 2 more to plats 3, 9, and 10. The grazing season terminated October 3. The sheep pastured were slaughtered and the weight of carcass and percentage of mutton determined.

The average results of the tests, which are discussed in detail, are shown in the following table, which gives the percentage of increase of hay and mutton produced on the different plats as compared with plat 6 taken as a unit. The average live weight, the average dressed weight, and percentage of mutton of the lots pastured on the different plats are also shown.

Average results of different methods of manuring pasture as shown by production of hay and mutton.

Plats.	Treatment.	Hay in		Mutton in		Hay consumed per pound of gain in live weight of sheep.	Average live weight of sheep.	Average dressed weight of sheep.
		excess of amount produced by plat 6.	excess of amount produced by plat 6.	Per cent.	Per cent.

a Decrease.

Some experiments on the fattening value of certain foods gathered by pigs, R. L. BENNETT (Arkansas Sta. Bul. 54, pp. 83-86).—The value of Spanish peanuts, chufas, and soy beans for pigs was tested. These crops were grown on sandy loam cotton soil, producing on an average 30 bushels of corn to the acre. The pigs were confined with movable fence on small areas of each crop. For purposes of comparison, one lot of pigs was fed corn in the ear. The test was made with 2 lots of 4 pigs, and 2 lots of 3 pigs. At the time of feeding the soy bean

Pods were well filled out and some were changing color. As the feeding progressed and the pods dried, the pigs showed a preference for the green ones, eating them first. The test was continued for 46 days with the lots fed peanuts, chufas, and corn. With the lot fed soy beans, it was continued for only 32 days, since the soy beans were eaten sooner than was expected.

The pigs fed peanuts, soy beans, and chufas gathered the crop on one-third of an acre. Those fed on corn consumed 23 bushels. The average results of the test are shown in the following table:

Results of pig-feeding experiment.

	Num- ber of pigs.	Weight of lot at be- ginning.	Weight of lot at end of 32 days.	Weight of lot at end of 46 days.	Gain of lot in 32 days.	Gain per pig per day in 46 days.
		<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>
Lot 1 (peanuts)	4	466	760	884	294	2.2
Lot 2 (soy beans)	4	499	590	91
Lot 3 (corn)	3	417	646	754	229	2.4
Lot 4 (chufas)	3	364	482	562	118	1.4

The estimated quantity of pork produced per quarter acre of peanuts was 313 lbs., chufas 138 lbs., and corn 109 lbs. "With the corn-fed pigs the ratio of gain to corn consumed is quite large, but the thrifty condition of the pigs and their size at the beginning of the test, and the short period of feeding, are doubtless the causes. The peanut fed pigs gained practically as much as the corn-fed pigs and harvested their own food."

The fat of the pigs fed soy beans and chufas was of about equal firmness, but not quite as firm as that of pigs fed corn. The fat of the pigs fed peanuts was soft and oily. When cooked, no difference could be detected in the flavor of the meat of the pigs in the different lots.

Feeding acorns, G. W. CARVER (*Alabama Tuskegee Sta. Bul. 1, pp. 6-9*).—The composition of acorns is quoted and compared with that of corn. The successful feeding of 400 pigs on acorns and kitchen slops is reported. The acorns were also fed to milk cows in place of grain with satisfactory results, 2 qt. or 5 lbs. being fed daily. "While the milk did not materially increase as to quantity, it greatly improved in the amount of butter fat." So far as observed there were no bad effects on the butter. Horses are also said to be fond of acorns, and a statement concerning their successful use as a poultry food is quoted.

"In feeding acorns there is this precaution necessary: Where large quantities are given, plenty of laxative food should be included in the ration, as they are rather binding in their nature and likely to produce harmful results. . . .

"In feeding them to hogs, we find that rather a soft, spongy flesh is produced with an oily-like lard that hardens with great difficulty and frequently not at all. This is readily overcome by feeding corn 2 or 3 weeks before butchering, although many hundred pounds of meat go into market without complaint that have never been topped off with corn."

Poultry notes, F. E. HEGE (*North Carolina Sta. Bul. 152, pp. 21*).—The bulletin describes a portion of the work of the poultry section of the station for the year ending July 12, 1898. The houses and appliances are described, as well as the diseases observed among the poultry and the treatment followed. A feeding experiment with ducks and 3 tests with chickens hatched in incubators are also reported.

Disease experiments (pp. 6-13).—Little disease was observed among the poultry. This is attributed to the fact that the fowls were kept clean and comfortable, the houses well cared for, and continual war waged on vermin.

A number of chickens were treated for diarrhea. From these cases and the experience of previous years—

“It seems that, if taken in time, a cleansing of the system by the use of either sweet oil or calomel, followed by soft food containing, say, 10 per cent black pepper (or less, if the fowl will not consume as much . . .), will almost invariably effect a cure, but if the trouble is not noticed at once cures are infrequent. What causes the occasional cases in the yard has not been determined, unless . . . the fowl in molting is naturally weaker than when in full feather. No severe cases have appeared except during the molting season.”

Several of the chickens suffered with sore head. Some of the cases were successfully treated with an application of copper sulphate.

“Sore head is a serious drawback to poultry raisers in the South and if the disease strikes a flock during June or July, nothing could do the fowls more damage, as it is extremely contagious, apparently healthy fowls one day being covered with sores on the head the next. . . .

“Sore head in winter is indeed a rare occurrence and that is another indication that stagnant blood is really the prime cause of the disease. Sulphur and salts both act on the system of the fowl, cleansing it from almost any lingering disease germs.”

Feeding powdered sulphur mixed with the morning food 3 times a week ($\frac{1}{2}$ lb. to each $\frac{1}{2}$ gal. of food) and adding $\frac{1}{4}$ lb. Epsom salts to the gallon of drinking water is regarded as a satisfactory preventive of sore head. This was followed from March 1 to October 1.

A number of cases of roup were also treated.

“There is no doubt that the colds which had developed into mild cases of roup were caused by the chickens roosting where the chilly night air was continually upon them. We . . . are satisfied that if the fowls are placed in positions not exposed to draughts the disease is not necessarily contagious. Previous experiments made by the writer in 1891 and 1892 fully convinced him of the foregoing. There can be little doubt that if a laxative had been given the subjects when first isolated and nostrils had been cleansed daily their period of confinement would have been decreased by several days.”

Feeding experiments with Pekin ducks (pp. 13-15).—Eighteen Pekin ducks were fed 56 days from the time they were hatched. At the beginning of the test the total food consisted of 4.4 oz. of meal and an equal amount of bran per head daily, while at the close of the test 6 lbs. 10 oz. of meal, 4 lbs. 3 oz. of bran, and 3 lbs. 5 oz. of bone were fed daily. In addition to the grain an amount of fine grit equal to one-sixth of the weight of the grain and chopped green clover equal to

one-fourth the bulk of the ration were also fed. All the feed was mixed with water to a crumbly mass and fed in troughs. No water was allowed except for drinking purposes.

The financial statement is based on corn meal at 1 ct., wheat bran at 0.9 ct., cut bone at 1 ct., and grit at 1 ct. per pound. Account was also taken of the value of the clover fed, the eggs set, and the food of the hens carrying the ducks. The ducks weighed 2 oz. when hatched and 4 lbs. 15½ oz. at the close of the test. The cost of a pound of gain was 5.05 cts. The ducks sold for 50 cts. each.

Incubator tests (pp. 16-22).—In the first test reported 86 strong chickens were hatched from 250 eggs. Accidental causes are believed to account for the apparently poor hatch. The chickens were fed for 8 weeks. During this time 13 chicks died. The average weight of the chickens when 8 weeks old was 1.49 lbs. Taking into account the cost of the food and eggs set, heat for the incubator, etc., the average cost of a pound of gain was 6.96 cts.

In the second test reported, 135 chickens were hatched from 200 eggs. The chickens were fed for 8 weeks, during which time 9 chickens died. The average weight of the chickens when 8 weeks old was 1.49 lbs. The average cost of a pound of gain was 6.42 cts. In this test a simple homemade brooder was used. It was heated with hot water. The total cost, including labor and lumber, was about \$3.

In the third test only 65 chickens were obtained from 200 eggs. Accidental causes were believed to account for the poor hatch. A plan is suggested for keeping a monthly record of a poultry yard.

Food supply, R. BRUCE (*London: Charles Griffin & Co., Ltd.; Philadelphia: J. B. Lippincott Co., 1898, pp. 159, figs. 76*).—This volume, which is described in the subtitle as "a practical handbook for the use of colonists and all intending to become farmers abroad or at home," contains chapters on climate and soil, drainage and rotation of crops, seeds and crops, vegetables and fruits, cattle and cattle breeding, sheep, pigs, poultry, horses, the dairy, the farmers' implements, and notes on the settler's home. In an appendix preserved and concentrated foods are treated of.

Concerning sitos [a prepared wheat food], E. CAPPELLETTI (*Ztschr. Untersuch. Nahr. u. Genussmtl., 1 (1898), No. 6, pp. 384-389*).—Sitos is a preparation of wheat made by splitting the grain lengthwise and removing the outer layer by a special process. It is made from hard Sardinian wheat (*Triticum durum*). Analyses of sitos, rice, and Italian paste are reported. The digestibility of each of the materials was tested with 3 men. The average coefficients of digestibility are shown in the following table:

Coefficients of digestibility of sitos, rice, and Italian paste.

	Nitrogen.	Fat.	Carbohydrates.	Ash.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Sitos	78.73	92.03	96.14	75.57
Rice	69.29	92.59	97.36	73.98
Italian paste	86.93	87.86	97.35	72.24

In each case the materials were cooked in a thick soup.

Directions for sampling foods, condiments, and commercial products, G. RUPP (*Anleitung zur Probecutnahme von Nahrungs- und Genussmitteln sowie Gebrauchsgegenständen*. Karlsruhe: F. Gutsch, 1899, pp. 40; *rev. in Ztschr. Untersuch. Nahr. u. Genussmitt.*, 2 (1899), No. 2, pp. 399, 400).

The adulteration of flour with rye, buckwheat, rice, barley, maize, beans, and potato starch, BALLAND (*Jour. Pharm. et Chim.*, 9 (1899), 6. ser., No. 5, pp. 239-243; 6, pp. 286-290).

The adulteration of coffee and tea, W. A. WITHERS and G. S. FRAPS (*North Carolina Sta. Bul.* 154, pp. 37-48).—The examination of a number of samples of coffee and tea is reported. The adulteration of these articles is discussed at some length.

Lessons in domestic science, ETHEL R. LUSH (*London and New York: The Macmillan Co.*, 1898, pt. 1, pp. 88, figs. 49; pt. 2, pp. 77, figs. 48).—These books are written to meet the requirements of different grades in English schools.

Food preservatives, A. HILL (*Jour. Roy. Agr. Soc. England*, 3. ser., 10 (1899), pt. 1, pp. 171-186).—This general discussion of the subject is from the author's presidential address before Section 1 (Sanitary Science and Preventive Medicine) of the Sanitary Institute Congress at Birmingham in 1898.

Maize and its uses, R. W. DUNHAM (*Jour. Roy. Agr. Soc. England*, 3. ser., 10 (1899), pt. 1, pp. 116-136).—The author discusses the botanical structure and food value of maize and compares it with other feeding stuffs.

The food value of fruits, W. H. JORDAN (*New York Agr. Soc. Rpt.*, 1897, pp. 577-584).—A popular discussion of the subject.

Food value and yield of Guinea grass (*Roy. Bot. Gard. Trinidad Bul. Misc. Inform.*, 3 (1898), No. 18, pp. 159-162).—The composition and yield of Guinea grass (*Panicum maximum*) is reported and the composition compared with that of clover hay, vetch, Bahama grass, and Para grass.

Wheat offals sold in Maine in 1898, C. D. WOODS (*Maine Sta. Bul.* 47, pp. 8).—This bulletin contains analyses of wheat bran, middlings, mixed foods, and other refuse milling products of wheat collected by the station in the State during 1898.

Feeding stuff inspection, C. D. WOODS (*Maine Sta. Bul.* 48, pp. 16).—The more important concentrated feeding stuffs are described, and the requirements of the feeding stuff law are briefly given.

The chemistry of peptic and tryptic digestion of protein, D. LAWROW (*Ztschr. Physiol. Chem.*, 26 (1899), No. 6, pp. 513-523).

On absorption in the small intestine, R. HÜBER (*Arch. Physiol. [Pflüger]*, 74 (1899), No. 5-6, pp. 246-271).—A second communication on this subject. A number of experiments are reported and discussed on theoretical grounds.

The carbon dioxide content of inspired air indoors and out of doors, K. B. LEHMANN, G. FUCHS, and H. SCHMIDT (*Arch. Hyg.*, 34 (1899), No. 4, pp. 315-320).

The use of the metabolism of energy in the animal body in computing correct feeding standards, C. LEHMANN (*Landw. Vers. Stat.*, 51 (1898), No. 2-3, pp. 185-188).—A controversial article.

Proceedings of the second convention of the Society for the Rational Feeding of Farm Animals (*Compt. Rend. 2me Congrès Soc. Aliment. Rat. Bétail*, 1898, pp. 146).—In addition to routine business, the report contains a number of special articles, among others experiments on fattening animals made in France and in foreign countries in 1897-98, the relative feeding value of hay and alfalfa, adulteration of feeding stuffs, and feeding race horses. Several articles on calf feeding are also reported and experiments with rabbits on the digestibility of different sorts of fodder beets and carrots.

Experiments on pork and beef as money crops for cotton farmers, R. L. BENNETT (*Sup. Circ. to Arkansas Sta. Bul.* 54, pp. 4).—Owing to the low price of cotton, attention is called to the fact that other crops may be more profitably grown if they are fed to pigs and steers. Results of tests at the station are cited in proof of this.

Poultry in Belgium (*U. S. Consular Rpts.*, 1899, No. 223, pp. 648, 649).—A brief

account is given of raising and marketing poultry in Belgium. When about 3 months old the chickens are confined in coops and fed ground buckwheat, mixed with milk, morning and afternoon, and at noon milk or milk and water. If the fowls refuse the food, they are not forced to eat, but are removed from the coop and killed, as they grow thin otherwise and lose market value. The fowls are generally kept in the fattening coops from 4 to 5 weeks.

DAIRY FARMING—DAIRYING.

The water content of butter, B. MARTINY (*Landw. Jahrb.*, 27 (1898), No. 6, pp. 773-963).—This is a very extensive compilation of analytical work bearing on the water content of butter in different countries. The work done at the Wisconsin, Vermont, Massachusetts, and Connecticut stations is included. Data for 20,706 analyses are brought together and classified by countries and in various other ways. A summary of the range and average water content for different kinds of butter is given as follows:

Summary of water content of butter.

	Number of samples.	Water content.			Range of water content.
		Lowest.	Highest.	Average.	
Fresh dairy or creamery butter (all countries):		<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Unsalted	831	6.86	27.51	14.10	20.71
Salted	17,332	3.84	22.12	13.55	18.28
Peasant butter (Germany):					
Unsalted	738	3.68	41.60	14.79	37.92
Salted	841	4.32	49.02	14.74	44.70
Butter packed for keeping (all countries)	113	5.06	21.30	10.73	16.24
Hamburg packing stock ("Packbutter")	819	16 —	24 +	23.00	12 +
Whey butter:					
Unsalted	30	10.09	20.68	15.58	10.59
Salted	2	14.05	14.73	14.39	.68
Total range and average	20,706	3.68	49.02	14.03	45.34

For fresh dairy and creamery butter the range and average of the water content are given by countries as follows:

Water content of dairy and creamery butter from different countries.

	Unsalted.				Salted.			
	Number of samples.	Lowest.	Highest.	Average.	Number of samples.	Lowest.	Highest.	Average.
		<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>		<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Germany	523	9.10	23.60	13.96	1,107	5.90	22.12	13.01
Austria	38	8.53	19.50	14.51				
Switzerland	9	6.80	15.40	12.70				
Italy	53	8.54	19.78	13.67	6	10.02	12.79	11.52
France	62	9.80	18.00	13.57	225	9.68	21.10	13.40
Netherlands	4	13.67	14.22	13.96	63	7.70	20.80	13.07
England	30	11.87	16.26	13.51	334	4.91	20.75	12.08
Denmark	93	12.73	19.85	15.16	9,847	8.98	19.88	13.99
United States	17	13.05	27.51	17.17	596	7.11	20.00	11.53
Australia and New Zealand	2	9.36	11.91	10.64	62	6.00	16.00	11.38
Sweden					4,423	8.87	20.22	13.66
Finland					438	8.10	15.30	11.18
Canada					207	3.84	19.70	8.97

Portions of the data are arranged to show the effect on water content, if any, of the season of the year, breed of cows, feed, methods of butter making, salting, keeping, and other factors; and based upon these considerations the author makes some deductions as to the limits of the allowable water content of different classes of butter. He concludes that, from the data at hand, salted or unsalted butter which contains more than 20 per cent of water has unquestionably been either very carelessly made or purposely adulterated, and accordingly should be excluded from public sale as not fulfilling the reasonable expectations of the consumer. Since the data for the better class of butter (from dairies and creameries) show that the averages for different countries do not exceed 14 per cent of water; that at present fully four-fifths of all the butter contains less than 16 per cent of water; that butter regarded as good only occasionally exceeds 15 per cent of water, and that an unusually high water content can be corrected by proper feeding or methods of making, the author concludes that commercial table butter should not contain, as a rule, more than 16 per cent of water, and that all butter which contains from 16 to 20 per cent of water should be classed as more or less inferior, according to its fat content—i. e., as cooking or baking butter.

Finally, a suggestion is made for the legal regulation of the sale of butter in Germany, defining butter and fixing the following limits: Butter fat, at least 80 per cent in table butter and 76 per cent in cooking or baking butter; nonfatty organic solids (casein, milk sugar, lactic acid, etc.), not exceeding 2 per cent; water, under 16 per cent in table butter and under 20 per cent in cooking or baking butter; salt, not over 3 per cent in table butter or over 5 per cent in cooking or baking butter.

The causes of the rancidity of butter, C. ANTHOR (*Ztschr. Analyt. Chem.*, 38 (1899), No. 1, pp. 10-20).—The author made a study of total acids, volatile acids, esters, etc., of sweet and sour cream butter when new and at different stages of rancidity. He finds that both sour-cream butter and rancid butter contain alcohol, and that all butters contain volatile bodies saponifiable by potash. Rancid butter also contains esters of the free volatile fatty acids, principally ethyl ester of butyric acid. The principal reason why a butter becomes rancid is said to be the intensive development of "bouquet," which soon renders the butter unfit for use, although the taste remains normal and the total acid is much below Stockmeier's maximum of 8. The rancid odor is caused principally by a mixture of small amounts of volatile fatty acids and ester. In distillation the butyric ester odor is at first very intense. As butter becomes older the development of bouquet reaches a maximum, after which it decreases nearly to zero. In this condition the butter is tallowy. Sweet-cream butter becomes rancid much more slowly than sour-cream butter and does not equal it in the development of bouquet.

The cause of the formation of these odors in the butter is attributed to micro-organisms which produce alcohol from the milk sugar, a cleavage taking place simultaneously in the glycerids, which yield acid for the formation of esters. As the glycerid of butyric acid is the least stable, this is usually principally affected. The freed glycerin undergoes various changes, forming aldehydes and keton-like bodies, according to Schmid¹ and Mayrhofer. The author coincides with the view of Schmid, that the processes of becoming rancid and of becoming sour are not identical. Rancidity of butter in the stage of development of bouquet is regarded as different from the rancidity of other fats, in which the odor is of less importance, and the fat is rendered unfit for food mainly by the irritating taste.

Tubercle bacilli in market butter, OBERMÜLLER (*Hyg. Rundschau*, 9 (1899), No. 2, pp. 57-79).—In a preliminary communication on this subject² it was reported that 14 samples of Berlin butter, tested by injecting 5 or 6 guinea pigs with each sample, were found to be infected with virulent tubercle bacilli. Every animal receiving injections of butter in the abdominal cavity showed signs of tuberculosis, and this was corroborated by numerous cultures from the affected parts, which showed tuberculosis in a high degree.

The present paper is partly controversial and discusses the earlier investigation in more detail, with a verification of the results on preserved specimens of affected parts of the animals. It also contains the results of tests, by means of guinea pigs, of 10 additional samples of first-quality butter procured from the same source as in the first investigation. Four samples showed positive evidence of the presence of true tubercle bacilli. Animals injected with other samples were made very sick, and cultures made from the slaughtered animals contained tubercle bacilli in some cases. It was found, in agreement with others, that the action of only slightly pathogenic bacteria was much intensified by the presence of butter fat. For this reason, the treatment of the melted butter in a centrifuge and the use of the sediment for injection is believed to give more reliable results than injection with butter directly.

The author states in conclusion that a large proportion of the butter samples examined by him contained tubercle bacilli, and the presence of these bacilli in butter in most cities is probably not infrequent. State control of dairy herds is strongly recommended.

Experiments with calcium chlorid for rendering heated milk suitable for cheese making, KLEIN and A. KIRSTEN (*Milch Ztg.*, 27 (1898), No. 50, pp. 785-787; 51, pp. 803-805).—This investigation was suggested by the practice of sterilizing milk for butter making and the resulting difficulty of using the skim milk for cheese making. Three series of experiments were made, including a large number of trials in

¹ Ztschr. Analyt. Chem., 37 (1898), p. 301.

² Hyg. Rundschau, 7 (1897), pp. 712-714.

each, separator skim milk being heated to 75° C. for 15 minutes in the first series, to 85° for 10 minutes in the second, and to 100° for 2 minutes in the third. In each experiment 20 liters of skim milk was used, varying quantities of calcium chlorid being added in different cases, and none in some cases. Cheese was made in each case.

In the first series, where the milk was heated to 75° C., it was found that there was little difficulty in making cheese from the milk, either with or without the addition of calcium chlorid, but the authors recommend adding to such milk the equivalent of 10 gm. of calcium oxid per 100 liters of milk, to facilitate the curdling.

The cheese made from milk heated to 85° C. and treated with calcium chlorid resembled in many respects that made in the first series of experiments. The yield of cheese was in all cases greater where the calcium chlorid was used than in the control experiments. The green cheese also contained more water, but even on the basis of dry matter the yield was greater. The greatest difficulty in making cheese from this kind of milk was found to be the time required for the complete separation of the whey from the curd.

The use of calcium chlorid was also found to restore the ability of milk heated to 100° C. to curdle, but to accomplish this in the same time 2½ times as much calcium chlorid was required as in the first series. The separation of the whey was very slow and difficult, and the curd itself was unusually rich in water, and was changed to a grayish-white appearance and a finely granulated condition, with very little tendency to adhere together. The addition of larger quantities of calcium chlorid improved the adhesive qualities of the curd, although it did not entirely remove the difficulty. Experiments made in subsequent heating to 40° C. to hasten the separation of the whey and to make the curd more adhesive resulted favorably, and this is to be the subject of further investigation.

In a later note in the same journal (No. 53, p. 840) it is stated that all difficulties in making cheese from milk heated to 85° have been overcome, and that the process is rendered as simple as ordinary cheese making. A description of the method is promised.

An inquiry concerning the source of gas and taint-producing bacteria in cheese curd, V. A. MOORE and A. R. WARD (*New York Cornell Sta. Bul.* 158, pp. 221-237, pl. 1).—A study was made of this trouble, which occurred at a cheese factory and was popularly supposed to be due to decomposed retained placentas. An examination of the gassy and tainted curd "showed that both the taint and the gas were caused by the same species of gas-producing bacteria, a micro-organism resembling very closely, if not identical with, *Bacillus coli communis*." Cheese made from sterilized milk inoculated with this bacillus developed the gassy curd and taint. A search for the source of this bacillus showed that it was not in the rennet or in the water used in the cleaning. A bacteriological examination was then made of the milk of the individual cows in the suspected dairy. This showed that the gas and

taint-producing bacteria were present more or less constantly in the milk of each animal, and that the milk of the cows which had suffered from retained placenta was, as a rule, no worse than that of the other cows. Examination of the dust and filth from the stable gave negative results, and the inference was reached that the bacteria had become colonized in the udders of certain of the cows. This, however, could not be positively determined.

The examination of the teats and udders of a number of cows which were slaughtered on account of tuberculosis (not from the infected dairy, however) showed that "bacteria were there and remained there after milking, ready to infect the milk of the next succeeding milking," but no gas-producing bacteria were found in any of the udders examined.

Two experiments were made to test the power of bacteria to pass from the intestines to the udder, the cows being given drinking water containing 1 to 2 qt. of a bouillon culture of *Bacillus prodigiosus* daily for nearly 2 weeks, and the milk examined for this organism with negative results. A repetition of the experiment, using cultures of the gas-producing bacillus from cheese curd, also gave negative results.

A technical description is given of the gas-producing bacillus, which is believed to be "closely related to, if it does not belong in, the colon group of bacteria."

Cleanliness in the stable and in the care of the cows is believed to be the best preventive of the trouble. The disinfection of the milk ducts by washing them out with a germicide by means of a milking tube, as reported by a German experimenter, was not successful in the hands of the authors.

Changes in fat during the ripening of cheese, A. KIRSTEN (*Ztschr. Untersuch. Nahr. u. Genussmitl.*, 1 (1898), No. 11, pp. 742-759).—Four sorts of cheese, Camembert, Neufchatel, Tilsiter fat, and Holland, were examined with reference to the changes in the fat. The fat was separated from the cheese with ether by triturating the ground or broken-up cheese in a mortar with ether, the free acids being neutralized with potassium hydrate. The mass was then shaken vigorously, the ether being renewed from time to time, and the shaking continued until the ether extract contained no trace of fat. The ether-fat layer was then separated by centrifugal force and the fat freed from the ether by distillation and dried in hydrogen at 100°. The volatile and the insoluble fatty acids and the saponification equivalent were determined in the fat, as well as the index of refraction. The cheese was further examined as to the solids-not-fat, ash, salt, and total nitrogen; and the solids-not-fat were examined for total solids, nitrogen, ash, and salt, and were extracted with water, the extract being examined for total solids, ash, and nitrogen in different forms.

The results showed that the fat separated from the different cheeses at different stages of ripening was very nearly uniform in composition. While a quantitative decomposition of the cheese fat is believed possible, these results indicate that where it takes place all parts of the fat

are uniformly decomposed. The view that the glycerids of the different fatty acids are associated with the ripening is thought to be disproved. The losses in absolute amount of fat during ripening were as follows: Camembert 0.12 per cent, Neufchâtel 0.85, Tilsiter 0.19, and Holland 0.57; and of ether extract: Neufchâtel 4.40, Tilsiter 2.96, and Holland 0.58 per cent. These losses the author regards as small and within control in the ripening room.

In discussing Weigmann and Baeké's paper (E. S. R., 10, p. 789) the author states that the formation of free nonvolatile fatty acids observed by them in ripe cheese is not a proof of a decomposition of the neutral fat of the cheese, since these could just as well have originated from decomposing nonfatty constituents, especially the albuminoids.

Changes in fat during the ripening of cheese, H. WEIGMANN (*Ztschr. Untersuch. Nahr. u. Genussmitl.*, 2 (1899), No. 1, pp. 31, 32).—The author takes exception to the above explanation of Kirsten of the free nonvolatile fatty acids found by Baeké and himself in cheese. He contends that numerous investigations have shown that fat is not formed from the albuminoids in cheese ripening, and that Colm has shown that in the cleavage of casein by hydrochloric acid the higher fatty acids are not formed. The formation of volatile fatty acids from casein is admitted, but no weight was placed by Weigmann and Baeké on the determination of these.

The author criticises Kirsten's results, claiming that the method of fat separation employed extracted only the unaltered fat of the cheese. He asserts that Kirsten's conclusions are not warranted, and that his paper does not change the status of the question.

Feeding dairy cows, T. L. HAECKER (*Minnesota Univ., Dept. Agr., Class Bul.*, pp. 20).—The author discusses the principles of feeding, the composition of feeding stuffs, and the application of these data. He presents in tables the composition of various feeding stuffs and their comparative money value, based upon timothy hay and bran at different prices, and upon their digestible protein content. The compounding of rations to meet the feeding standards is discussed and illustrated by examples.

"That generous feeding pays is clearly illustrated in our record for the 5 years ending December 30, 1897. During the years 1893, 1895, 1896, and 1897 cows were fed all they would take, while during the year 1894 they were fed light.

Field of milk and butter by herd.

Year.	Yield of—		Cost of 1 lb. of butter.
	Milk.	Butter.	
	<i>Pounds.</i>	<i>Pounds.</i>	<i>Cents.</i>
1893	6,407	364	10.6
1894	4,969	271	10.9
1895	7,418	352	8.0
1896	7,454	349	6.3
1897	6,962	351	5.4

"These are averages of the entire herd, and show that during the 4 years when receiving all they would eat up clean they averaged 354 lbs. of butter each, while the average yield for the year 1894, when on comparatively light feed, was only 271 lbs. The cost of production was also the greatest that year."

A new scale of points for judging dairy cows, C. L. BEACH (*Hoard's Dairyman*, 30 (1899), No. 9, pp. 176, 177, fig. 1).—A description of the scale, with examples of its use on the cows of the Storrs Agricultural College.

Colostrum, E. UNGER (*Arch. Path. Anat. u. Physiol.* [Virchow], 151 (1898), No. 1, pp. 159-175, pl. 1).—A résumé of the literature of colostrum and a study of the physiological process of colostrum formation on human subjects.

Researches on milk—determination of watering, A. VILLIERS and M. BERTHAULT (*Bul. Soc. Chim. Paris*, 19 (1898), No. 7, pp. 305-310).

A modification of the Babcock milk test, M. SIEGFELD (*Molk. Ztg.*, 13 (1899), No. 4, pp. 51, 52).—To avoid cloudiness of the fat column and make the line of demarcation more distinct, it is proposed to fill the bottles, after the first whirling, with sulphuric acid of 1.5 sp. gr. instead of with water. It is noted also that a clear fat column can be obtained with one whirling by using amyl alcohol and filling with sulphuric acid of 1.5 sp. gr. Several comparative tests are reported.

The determination of the dirt in milk, R. EICHLÖFF (*Milch Ztg.*, 28 (1899), No. 5, pp. 65, 66).—A study was made of the Stutzer method in common use, which resulted in showing that method to give too low results.

The sterilization of milk, MACFADYEAN and HEWLETT (*Trans. British Inst. Precent. Med.*, 1897; *abs. in Hyg. Rundschau*, 9 (1899), No. 6, p. 308).—The authors discuss the pasteurization of milk and the efficiency of a temperature of 55 to 65 C. in destroying disease germs. They describe an apparatus which consists of a system of spiral tubes through which the milk passes and in which it is alternately heated to about 70° C. and cooled. Milk can be effectively pasteurized on a commercial scale with this apparatus without any change in taste or appearance. Special experiments with pure cultures of pathogenic bacteria showed that these were killed by the treatment.

Embalming milk (*Hoard's Dairyman*, 30 (1899), No. 9, p. 167).—Remarks on the use of "Freezenc" as a milk preservative. The active principle of this preservative is said to be formic aldehyde.

Bacteria in lacteal secretion, U. TRINCI (*Abs. in Jour. Hyg.*, 33 (1898), No. 1157, p. 559).

Biological studies of Clostridium licheniforme and Paraplectrum foetidum, H. WEIGMANN (*Centbl. Bakt. u. Par.*, 2. Abt., 4 (1898), No. 22, pp. 820-834, pls. 2).

Denaturation of margarin, V. MAINSBRECCQ (*Bul. Assoc. Belye Chim.*, 12 (1898), No. 5-6, pp. 185, 186).

A new method of butter making (*Milch Ztg.*, 27 (1898), No. 53, p. 842).—A description of the so-called Norstedt method. The butter is washed thoroughly with cold water as soon as it is churned, and immediately worked and salted. Butter made by this method was found to contain less casein and slightly more water than ordinary butter. The butter is deficient in aroma, as would be expected, but has the advantage of unusual keeping qualities.

Whey butter (*Queensland Agr. Jour.*, 4 (1899), No. 2, pp. 112, 113).—Popular directions for making whey butter. "In the experience of the writer, the whey obtained from 60 gal. of milk is sufficient to afford 1 lb. of finished butter."

Passage of the reaction of cotton-seed and peanut oil in butter, F. WERENSKIOLD (*Jahresber. Öffentl. Förd. Landw. Norwegen*, 1897; *abs. in Jour. Soc. Chem. Ind.*, 18 (1899), No. 2, p. 162).—Araclidic acid could not be detected in butter after feeding cows on ground peanut cake (1 kg. per day). When the same amount of cotton-seed meal was given, the butter obtained thereafter showed the reaction of the corresponding oil. The cotton-seed oil reaction was never observed except after feeding with cotton-seed meal.

The systematic butter exhibitions in Denmark and Sweden, R. EICHLÖFF (*Molk. Ztg.*, 13 (1899), No. 1, pp. 3, 4).—A description of these exhibitions and their operation, drawn from personal observations of the author.

The preparation of Tilsiter cheese, R. EICHLÖFF (*Molk. Ztg.*, 13 (1899), No. 2, pp. 19, 20).—A description of the methods employed in making this kind of cheese.

A new alcoholic fermentation product from skim milk and whey, A. G. EKSTRAND (*Milch Ztg.*, 28 (1899), No. 2, pp. 21, 22).—A note on a new cheap alcoholic beverage.

AGRICULTURAL ENGINEERING.

Farm drainage—why and how, J. J. W. BILLINGSLEY (*Drainage Jour.*, 21 (1899), No. 4, pp. 90-94).—A popular discussion of the subject.

Automatic division of irrigation water, W. M. BRISTOL (*Pacific Rural Press*, 57 (1899), No. 10, p. 145, figs. 2).—The construction and mode of operation of an adjustable automatic weir in use in the Highland district, San Bernardino County, California, are described.

Plows in Italy, H. A. JOHNSON (*U. S. Consular Rpts.*, 1899, No. 223, pp. 614-616).—An account of field trials of plows made by three German firms.

Agricultural machines competing at Paris, M. RINGELMANN (*Jour. Agr. Prat.*, 1899, 1, No. 13, pp. 464-470, figs. 6).

Trials of farm machinery, 1898, I. SVERDRUP ET AL. (*Christiania*, 1899, pp. 69, ill.).—The report gives detailed results of working trials with farm machinery conducted by the Royal Society for Norway's Weal, and includes trials of 7 two-horse and 9 one-horse mowers, 10 horse rakes, and 4 hay tedders. Nearly all the leading American farm-machinery firms were represented, and the machines awarded first diplomas were, without an exception, of American manufacture. The working trials were made according to a carefully prepared plan and scores given for quality of work done, for work in relation to draft, construction, and durability, and attention required during operation.—F. W. WOLL.

Agricultural electrotechnics, R. H. THURSTON (*Science, n. ser.*, 9 (1899), No. 222, pp. 480, 481).—A review of an article by P. Renaud on agricultural electrotechnics in Germany and its future in France and her colonies, published in *Bul. Soc. Encouragement Ind. Nat.*, 1899, Jan., p. 15.

Cigar leaf-curing barn (*Queensland Agr. Jour.*, 4 (1899), No. 2, p. 107).—Brief directions for constructing a tobacco barn.

STATISTICS—MISCELLANEOUS.

Tenth Annual Report of Alabama College Station, 1897 (*Alabama College Sta. Rpt.*, 1897, pp. 28).—This contains brief outlines of the work of the different departments and a financial statement for the fiscal year ending June 30, 1897.

Organization and work of the Tuskegee Experiment Station, G. W. CARVER (*Alabama Tuskegee Sta. Bul.*, 1, pp. 3-5).—The station staff, the act of the Alabama legislature establishing the station, and brief notes on the proposed work of the station are given.

Sixteenth Annual Report of New York State Station, 1897 (*New York State Sta. Rpt.*, 1897, pp. 661).—This contains the report of the treasurer for the year ending September 30, 1897, a meteorological record for the year, and reprints of Bulletins Nos. 117-142 of the station, excepting Nos. 120 and 122, on the following subjects: Treatment of leaf spot in plum and cherry orchards in 1896 (E. S. R., 9, p. 148); alfalfa (E. S. R., 9, p. 133); the downy mildew of the cucumber, what it is, and how to prevent it (E. S. R., 9, p. 248); spray pumps and spraying (E. S. R., 9, p. 262); spraying potatoes on Long Island in the season of 1896 (E. S. R., 9, p. 765); anthracnose of the black raspberry (E. S. R., 9, p. 762); forcing tomatoes, comparison of methods of training and benching (E. S. R., 9, p. 1051); notes on a tomato disease (E. S. R., 9, p. 1058); feeding experiments with chicks and capons (E. S. R., 9, p. 1076); strawberries

in 1897 (E. S. R., 9, p. 1052); variety tests with raspberries, blackberries, and dewberries (E. S. R., 9, p. 1052); analyses of commercial fertilizers for 1897 (E. S. R., 9, p. 1042; 10, p. 36); a bacterial disease of sweet corn (E. S. R., 9, p. 1056); results with oat smut in 1897 (E. S. R., 9, p. 1060); the source of milk fat (E. S. R., 9, p. 1083); spraying in 1897 to prevent gooseberry mildew (E. S. R., 9, p. 1061); the composition and production of sugar beets (E. S. R., 10, p. 115); inspection of nurseries and treatment of infected nursery stock (E. S. R., 10, p. 468); commercial fertilizers for potatoes (E. S. R., 10, p. 431); experiments and observations on some diseases of plants (E. S. R., 10, pp. 452, 453, 454); plant lice, descriptions, enemies, and treatment (E. S. R., 10, p. 167); wood ashes and apple scab (E. S. R., 10, pp. 437, 452); digestion and feeding experiments (E. S. R., 10, p. 476); report of the director of New York State Station (E. S. R., 10, p. 498).

Seventeenth Annual Report of Ohio Station 1898 (*Ohio Sta. Rpt. 1898, pp. XXIII, map 1*).—This contains reports of the board of control, the treasurer for the fiscal year ending June 30, 1898, and the director, including a brief outline of station work for the year, a subject list of Bulletins 85-95, a list of the publications received during the year, and acknowledgments of miscellaneous donations.

Tenth Annual Report of Texas Station, 1898 (*Texas Sta. Rpt. 1898, pp. 1111-1144, pls. 3*).—This consists of a report by the director on the work of the college and substations, brief reports by the heads of departments, financial statements for the fiscal years ending June 30, 1897 and 1898, and an appendix containing a bibliography of agricultural publications.

Tenth Annual Report of West Virginia Station, 1897 (*West Virginia Sta. Rpt. 1897, pp. 66*).—This contains a financial statement for the fiscal year ending June 30, 1897, and reports by the director, agriculturist and horticulturist, entomologist (p. 1067), and chemist, reviewing the different lines of station work for the year.

An effort to help the farmer, I. P. ROBERTS (*New York Cornell Sta. Bul. 159, pp. 241-268*).—This is the fifth report of progress of the State extension work in agriculture. Part I deals with the investigational work of the station already reported in bulletins and that under progress, correspondence work, and itinerant teaching by means of schools and lectures; Part II deals with the nature-study and reading-course work. The previous reports are given in Bulletins 110, 122, 137, and 146 of the station (E. S. R., 8, pp. 135, 740; 9, p. 699; 10, p. 498).

Beet-sugar manufacture in Sweden, 1896 to 1897 (*Tidskr. Landtmän, 19 (1898), No. 2, pp. 30-32*).—This article gives statistics on the production of beet sugar in Sweden for the year ending September 1, 1897. Nineteen factories were in operation and 890,240.4 metric tons of beets were worked, being an average of 46,855 tons per factory. The total yield of sugar was 105,556.2 tons, of which 94,261 tons were first sugars, 9,649.5 seconds, and 1,645.7 tons thirds and fourths. Besides the sugar 25,615.8 tons of molasses were produced. The yield of sugar was 11.86 per cent of the beets worked; the first sugars amounted to 10.59 per cent of the beets; the seconds to 1.08 per cent, and the thirds and fourths to 0.19 per cent. The yield of molasses was 2.88 per cent of the beets. The average sugar content of the beets, as determined by means of the polariscope, was 13.56 per cent, the maximum being 14.59 and the minimum 12.26 per cent. The number of tons of beets worked was 66 per cent greater than in 1895 and the amount of sugar obtained was 70 per cent greater.—F. W. WOLL.

NOTES.

GEORGIA STATION.—A department of biology has recently been created in connection with the department of horticulture. A laboratory has been equipped for the study of injurious insects and fungi, and material additions to the scientific library have been made. The life histories of certain injurious insects are being studied, as well as methods for their control.

ILLINOIS UNIVERSITY AND STATION.—The last general assembly of Illinois voted \$150,000 to erect and equip a building for instruction and investigation in agriculture at the University of Illinois. It also enacted that one-half of the funds arising from the land-grant act of 1862 and from the second Morrill bill of 1890 should be devoted to instruction in technical agriculture.

NEBRASKA STATION.—At a meeting of the board of regents of the University of Nebraska, held April 18-19, the office of assistant director of the station was created, and T. L. Lyon, agriculturist of the station, was appointed to the position. On account of lack of funds to carry into effect the purposes of the board in respect to the division of animal husbandry, the board was obliged to discontinue its temporary arrangement with Mr. C. H. Elmendorf, and ordered that the division of animal husbandry be placed in charge of the division of agriculture.

NEW YORK CORNELL UNIVERSITY.—The State assembly recently appropriated \$35,000 to the College of Agriculture of the University for extension work in agriculture.

NEW YORK STATE STATION.—As a result of civil-service examination, Frederick H. Blodgett, B. S., has been selected as assistant botanist and entomologist at the branch station at Jamaica, Long Island, and has entered upon his work. The State legislature has passed and the Governor approved the following bills: (1) Renewing the regular annual appropriation of \$50,000 for the station; (2) renewing the appropriation of \$10,000 for fertilizer analysis for the current year; (3) changing the fertilizer law for the next year to require licensing each brand sold in the State at a cost of \$20 per brand, the tax, or so much of it as needed, to pay expenses of collection of samples and analysis by the station; (4) placing sale of concentrated feeding stuffs under station control, requiring dealers to pay a tax of \$25 per brand; (5) giving appropriation of \$3,500 for constructing addition to cattle barn and other repairs; (6) appropriating \$1,000 for inspection of Paris green and other insecticides.

WISCONSIN UNIVERSITY AND STATION.—Arthur G. Hopkins, D. V. M., has been appointed veterinarian of the agricultural college and experiment station.

WYOMING STATION.—Aven Nelson, botanist of the station, left Laramie early in June on an extended botanical survey of the Yellowstone National Park and the adjacent forestry reserves. In addition to large collections of the entire flora a careful study of the forage plants and range conditions is contemplated.

INSPECTION OF NURSERIES AND NURSERY STOCK IN INDIANA.—The legislature of Indiana has passed a law for the inspection of nurseries and nursery stock.

ERRATUM.—In the abstract of Bulletin 121 of the California Station (E. S. R., 10, p. 617) the difference in the moisture content of cultivated and uncultivated apricot orchards to a depth of 6 ft. was erroneously stated to be 244 *pounds* per acre instead of 244 *tons*.

NECROLOGY.—Dr. A. W. Chapman, the well-known Southern botanist, died suddenly at his home at Apalachicola, Florida, April 6, 1899, in his ninetieth year. His *Flora of the Southern United States* is well known to all systematic botanists.

Charles Naudin, a distinguished botanist and a member of the Institute of France, died March 19, 1899, in his eighty-fourth year. He was director of the experimental gardens at Villa Thuret, Antibes, an adjunct of the *Jardin des Plantes*, Paris. His work in horticulture, and especially his elaboration and elucidation of the cultivated species and varieties of cucurbits, gives him rank among the greatest garden botanists of the century.

Prof. C. Scheibler, the well-known sugar chemist, died at Berlin, April 2, 1899, aged 72 years. While distinguished mainly for his contributions to the chemistry of sugar and sugar-making, Professor Scheibler carried out important investigations in other lines, his work on phosphatic slags being of especial value to agriculture.

Prof. G. H. Wiedemann, the distinguished chemist and physicist and editor of *Wiedemann's Annalen* (*Annalen der Physik und Chemie*), died at Leipsic March 24, 1899, in the sixty-third year of this age.

EXPERIMENT STATION RECORD.

VOL. X.

No. 12.

With the present number the tenth volume of the Experiment Station Record is brought to a close. An indication of the ground which it covers, as compared with the preceding volume, is furnished by the following table:

Publications abstracted.	Volume IX.	Volume X.
Station reports	56	35
Station bulletins	317	361
Publications of United States Department of Agriculture	201	172
Foreign articles	842	1,224
Total number of articles	1,810	2,023
Classified as follows:		
Chemistry	121	150
Botany	86	127
Fermentation and bacteriology	28	27
Zoology	31	23
Meteorology	57	46
Air, water, and soils	72	86
Fertilizers	85	109
Field crops	153	236
Horticulture	138	173
Forestry	16	34
Seeds and weeds	41	37
Diseases of plants	107	180
Entomology	252	202
Foods and animal production	186	223
Dairy farming and dairying	151	168
Veterinary science	134	86
Technology	11	6
Agricultural engineering	38	28
Statistics	103	82

The present volume contains 881 pages of abstracts, representing 57,230 pages in the original publications. In addition to these abstracts the volume contains the titles of 1,820 articles, mostly foreign, which are briefly noted, but not abstracted. There are also 14 editorials, occupying 24 pages; 9 special articles, occupying 94 pages, and 104 station and miscellaneous notes, occupying 17 pages.

The subject index, comprising this last number of the volume, has been made on the same general plan as that for previous volumes. The increased amount of material covered by the tenth volume has resulted in enlarging the index number considerably, since, as heretofore, the aim has been to index the contents in sufficient detail to serve as a guide to the publications reviewed.

As the Experiment Station Record was established soon after the agricultural experiment stations in the United States had completed their organization or reorganization under the Hatch Act, it contains an account of practically everything which the stations have done during the ten years in which they have received the support of the National Government. It would be interesting to review the history of their operations during this period, and to show in some detail how their operations have increased in number, variety, and importance; but this is too large a task to be undertaken at this time. There are, however, a few salient features of the development of the experiment station enterprise in this country to which it may be well to call attention in closing our record of their operations during the first decade under the Hatch Act.

The most obvious indication of the success of experiment stations as a means for improving agricultural conditions in this country is the steady increase in the number of stations and station officers, and in the amount of financial support which they have received from the National and State governments. In the first volume of the Record (p. 117) it is stated that in 1889 there were 46 stations in the United States receiving an aggregate revenue of about \$725,000, of which \$600,000 was appropriated from the National Treasury and \$125,000 was received from State governments and other local sources. The total number of persons engaged in the work of the stations and at this Office that year was 402. In 1898, the last year for which statistics have been compiled, the total number of stations was 54. Their total income was somewhat over \$1,200,000, of which \$720,000 was received under the Hatch Act (in addition to \$35,000 for this Office) and \$480,000 from State governments and other local sources. The number of officers had increased to 669.

With the increase in the number of the stations and the enlargement of their resources there has been a corresponding increase in the number and variety of their publications, and these have been more thoroughly distributed each year. Besides the vast amount of agricultural information which has thus been generally diffused among our farmers, either directly through station publications or indirectly through the public press, more than fifty books on strictly agricultural subjects have been written by station men during the past ten years, and the results of the work of the stations are being largely incorporated in books whose authors are not connected with the stations. It requires only a superficial retrospect to discover a very remarkable difference in the freshness of material and the thoroughness of treatment of the published information available to our farmers ten years ago and that which is at their command to-day. It is most encouraging to observe that, despite the pessimistic predictions in certain quarters, the output of carefully prepared books for the farmer's use has notably increased within the past few years, and American books for the American farmer are written from an American standpoint and on the basis of accurate information obtained by American investigators.

It is evident that the results of experiment station work are beginning to have a broad effect upon our agriculture. This is seen in such matters as the more intelligent use of fertilizers, the reorganization of dairy farming and dairying on a scientific basis, and the widespread use of fungicides, insecticides, and other means for the repression of diseases of plants and insect pests. Very largely under the guidance of the stations the diversification of agriculture is proceeding in many regions where hitherto one or two crops have been the main reliance of the farmer. Much has also been accomplished in showing how former wasteful methods of farm management may be done away with, and how a variety of by-products of the farm may be utilized to reduce the net expense of the production of the great agricultural staples.

Ten years ago we were obliged to rely very largely on foreign sources for information regarding the composition and digestibility of feeding stuffs, but to-day we have abundant American data for the compilation of standard works on the feeding of animals under American conditions, and along with the more scientific study of animal nutrition there has been a large amount of painstaking and useful investigation of the practical and economic usefulness of a great variety of American feeding stuffs in all sorts of combinations. And going somewhat outside of the range of work for which our stations were originally established, an increasing amount of study has been devoted to the problems of human nutrition. Thousands of analyses of American food materials have been made, a considerable number of dietary studies have been conducted, and somewhat elaborate studies on metabolism and the conservation of energy in the human organism have been prosecuted with marked success. Congress and some of the State legislatures have recognized this as a legitimate sphere for the work of the stations, and the direct bearing which much of this investigation has upon the more purely agricultural problems is each year more clearly recognized.

The ten volumes of the Record just completed contain abstracts of 3,063 bulletins and 394 reports of American experiment stations, 900 publications of the United States Department of Agriculture, and 4,323 articles relating to agricultural investigation at experiment stations and similar institutions in foreign countries. These abstracts occupy 6,994 pages of the Record, and required in their preparation the reviewing of 285,623 pages in the original publications. The bibliography of the current literature is rendered more comprehensive by the noting of 14,539 articles, mostly foreign, which are either not abstracted or only quite briefly. The original articles in the Record, consisting of 167 editorials and 78 special articles, comprise 1,285 pages. The news items and miscellaneous notes, of which there are a total of 1,069, occupy 203 pages. This material has been indexed with sufficient detail to make it quite convenient of reference in the 10 index numbers, including both author and subject entries, which comprise nearly 900 pages of double-column matter.

INDEX OF NAMES.

- Aaenestad, S., 432.
 Abbe, C., 419.
 Abbey, G., 653, 761, 765.

INDEX OF SUBJECTS.

	Page.		Page.
Abortion, epizootic, etiology.....	497	Eolosomine, composition.....	515
in cows.....	89E, 896	<i>Eolus pyroblaptus</i> , notes.....	975
treatment.....	95	Aerometer with temperature correction	
Ind.....	296	scale.....	920
N. J.....	495	Aeronautical conference, international, U.	
Absorption in the small intestine.....	1089	S. D. A.....	323
<i>Acacia arabica</i> , planting in Australia.....	443	<i>Esculus paria</i> , notes, U. S. D. A.....	516
<i>lobbeck</i> , analyses.....	678	<i>Ethyletera lineata</i> , notes.....	372
<i>molissima</i> in California.....	856	<i>Agaricus adiposus</i> , notes.....	653
<i>Acanthoderes quadrigibbus</i> , notes.....	168	<i>arvensis</i> , notes, U. S. D. A.....	551
Acclimation fever. (See Texas fever.)		<i>campestris</i> , notes, U. S. D. A.....	551
<i>Acer negundo</i> , notes.....	725	<i>nelleus</i> , affecting chestnuts.....	59
Acetate of copper vs. Bordeaux mixture for		Age, effect on egg production, Utah.....	77
grape <i>Peronospora</i>	364	Agitator electric.....	717
Acid butyrometric method for determina-		Agricultural—	
tion of fat in cream.....	91	analysis, international agreement.....	19
phosphate, analyses, Conn. State.....	230	uniformity of methods.....	413
Mass. Hatch.....	428	and dairy instruction, apprenticeships.....	98
vs. raw bone meal for cot-		appropriation bill.....	801
ton, Ga.....	140	association in Scandinavia.....	198
Aconite, notes, U. S. D. A.....	516	bacteriological laboratory at St. Peters-	
<i>Aconitum columbianum</i> , notes, U. S. D. A.....	516	burg, report.....	322, 1016
<i>Acoptus suturalis</i> , notes.....	168	calendar, Danish.....	98
Acorns, analyses, Ala. Tuskegee.....	1086	chemical laboratory at Helsingfors, re-	
for pigs, Ala. Tuskegee.....	1086	port.....	116
<i>Acridium purpuriferum</i> , notes, U. S. D. A.....	61	work in Scandinavia.....	21
<i>Actinella linearifolia</i> , notes, U. S. D. A.....	147	chemistry, progress.....	605
Actinometer, absolute.....	327	text-book.....	717
Actinomycosis, etiology.....	495	College and Experimental Farm for	
in horses.....	496	Nova Scotia.....	1000
man.....	496	at Aas, Norway, report.....	98
notes, Nebr.....	296	Council of Russia, proceedings.....	398
<i>Adalia bipunctata</i> , melauism, U. S. D. A.....	1060	counselors in Scandinavia.....	198
<i>Adelonycteris fuscus</i> , notes.....	25	Department of Finland, report.....	798
<i>Adimonia caricollis</i> , notes, Mich.....	169	Norway, report.....	98, 798
<i>tanacetii</i> , notes, U. S. D. A.....	65	education in Denmark.....	198
Adulteration of bone superphosphates.....	1003	Russia.....	500
butter.....	821	Spain.....	198
coffee.....	1089	reading courses.....	1
dairy products.....	492	electro technics.....	1097
fats and oils.....	884	engineering, abstracts of articles.....	195,
flour.....	1089	396, 597, 695, 795, 897, 1097	
foods, U. S. D. A.....	872	experiment station at Vyatka, Russia,	
preserved food.....	80	report.....	898
sumae.....	1005	in Alaska.....	701
tea.....	1089	of Poltava, report.....	798
vinegar, N. C.....	1077	stations in Japan.....	101
wheat flour.....	80	exposition of Kiev, report.....	1019
<i>Aecidium anchuse</i> , notes.....	316	holdings in Germany.....	198
<i>berberidis</i> , notes.....	316	implements, tests.....	599, 1097
<i>cathartica</i> , notes.....	316	improvements in Russia.....	198
<i>frangulae</i> , notes.....	316	industries of Russia, report.....	1039
<i>grossulariae</i> , notes.....	561	institutions in Denmark.....	98, 198
